<b>Foreword</b>	<b><i>xi</i></b>
-----------------	------------------

<b>Preface</b>	<b><i>xiv</i></b>
----------------	-------------------

## **Invited Contributions**

Jacques Demongeot, Alexandra Henrion-Caude, Athanase Lontos and Emmanuel Promayon. <i>General architecture of a genetic regulatory network. Applications to embryologic control</i> (full article)	1
David Harel. <i>Can we Computerize an Elephant?</i> (abstract)	9
Takashi Ikegami. <i>Do we need a theory in the Era of Massive Data Flow?</i> (abstract)	10
Stuart Kauffman. <i>Answering Descartes: Beyond Turing</i> (full article)	11
James D. Murray. <i>On the Growth of Brain Tumours: enhancing imaging techniques, highlighting limitations of current imaging, quantifying therapy efficacy and estimating patient life expectancy</i> (full article)	23
Jordan Pollack. <i>Prospects for Machine Embryogenesis</i> (abstract)	27
Steen Rasmussen, Pierre-Alain Monnard, Martin Hanczyc, Anders Albertsen, James Boncella, Eva Bonzli, Filippo Caschera, Mark Dorr, Harold Fellermann, Maik Hadorn, Wendie Jørgensen, Philipp Löffler, Sarah Maurer, Kent Nielsen, Pernille Pedersen, Carsten Svaneborg, Michael Wamberg, Rafal Wieczorek and Hans Ziock. <i>A review of one approach to bottom up assembly of minimal life</i> (abstract)	28
Ricard V. Solé and Javier Macia. <i>Synthetic biocomputation: the possible and the actual</i> (full article)	29
Susan Stepney. <i>ALife: a tension between biology and software engineering</i> (abstract)	37
Eric F. Wieschaus, Adam C. Martin, Bing He, Matthias Kaschube and Oleg Polyakov. <i>The mechanics of shape change in the Drosophila embryo</i> (abstract)	38

## **Refereed Articles**

Davide Agostini, Jole Costanza, Vincenzo Cutello, Luca Zammataro, Natalio Krasnogor, Mario Pavone and Giuseppe Nicosia. <i>Effective calibration of artificial gene regulatory networks</i> (full article)	39
Jordi Arranz, Jason Noble and Eric Silverman. <i>The origins of communication revisited</i> (full article)	47
David Balduzzi. <i>Detecting emergent processes in cellular automata with excess information</i> (full article)	55
David J. Barnes and Dominique Chu. <i>Walking, hopping and jumping: a model of transcription factor dynamics on DNA</i> (full article)	63

<i>Artificial gene regulatory networks and spatial computation: A case study</i> (full article)	
Luisa Damiano, Antoine Hiolle and Lola Cañamero. <i>Grounding synthetic knowledge: An epistemological framework and criteria of relevance for the synthetic exploration of life, affect and social cognition</i> (full article)	200
Alastair Droop and Simon Hickinbotham. <i>Application of small-world mutation topologies to an Artificial Life system</i> (abstract)	208
Matthew D. Egbert and Xabier E. Barandiaran. <i>Quantifying normative behaviour and precariousness in adaptive agency</i> (full article)	210
Mehmet D. Erbas and Alan F. T. Winfield. <i>On the emergence of structure in behaviours evolved through embodied imitation in a group of robots</i> (full article)	218
Alessandro Filisetti, Alex Graudenzi, Roberto Serra, Marco Villani, Davide De Lucrezia and Irene Poli. <i>The role of energy in a stochastic model of the emergence of autocatalytic sets</i> (full article)	226
Jonathan M. Fisher and Jason H. Moore. <i>Distinguishing the effects of epistasis and pleiotropy using a variant of the NK model</i> (full article)	234
Regina Frei. <i>A complex systems approach to education in Switzerland</i> (full article)	242
Tom Froese, Nathaniel Virgo and Takashi Ikegami. <i>Life as a process of open-ended becoming: Analysis of a minimal model</i> (full article)	250
Philip Gerlee and Torbjörn Lundh. <i>Urdar - an artificial ecology platform</i> (abstract)	258
Amr S. Ghoneim, Daryl L. Essam and Hussein A. Abbass. <i>On computations and strategies for real and artificial systems</i> (full article)	260
Chris Gordon-Smith. <i>Non-template molecules designed for open-ended evolution</i> (full article)	268
Laura M. Grabowski, David M. Bryson, Fred C. Dyer, Robert T. Pennock and Charles Ofria. <i>Clever creatures: Case studies of evolved digital organisms</i> (full article)	276
Robin Gras, Abbas Golestani, Meisam Hosseini Sedehi, Marwa Khater, Yasaman Majdabadi Farahani, Morteza Mashayekhi, Sina Md Ibne, Elham Salehi and Ryan Scott. <i>EcoSim: an individual-based platform for studying evolution</i> (abstract)	284
Andrew Guest, Andrew Sapeluk, Alan Winfield and James Bown. <i>Promoting meme diversity and transmission fidelity in artificial proto-cultures</i> (full article)	286
Yukio-Pegio Gunji, Hisashi Murakami, Takayuki Niizato, Andrew Adamatzky, Yuta Nishiyama, Koichiro Enomoto, Masashi Toda, Toru Moriyama, Tetsuya Matsui and Kojiro Iizuka. <i>Embodied swarming based on back propagation through time shows water-crossing, hourglass and logic-gate behaviors</i> (full article)	294
Heiko Hamann, Thomas Schmickl and Karl Crailsheim. <i>Explaining emergent behavior in a swarm system based on an inversion of the fluctuation theorem</i> (full article)	302
Taichi Haruna. <i>Global structure of directed networks emerging from a category theoretical formulation of the idea "Objects as processes, interactions as interfaces"</i> (full article)	310
Inman Harvey. <i>Opening stable doors: complexity and stability in nonlinear systems</i> (full article)	318

Mark Hatcher, Wolfgang Banzhaf and Tina Yu. <i>Bondable cellular automata</i> (full article)	326
Simon Hickinbotham, Susan Stepney, Adam Nellis, Tim Clarke, Ed Clark, Mungo Pay and Peter Young. <i>Embodied genomes and metaprogramming</i> (full article)	334
Imad Hoteit, Nawwaf Kharma and Luc Varin. <i>A gene regulatory network design of a synchronous single-input delay flip-flop</i> (full article)	342
Emmanouil Hourdakis and Panos Trahanias. <i>Computational modeling of online reaching</i> (full article)	348
Tim Hoverd and Susan Stepney. <i>Energy as a driver of diversity in open-ended evolution</i> (full article)	356
Takashi Ikegami, Mizuki Oka and Hirotake Abe. <i>Autonomy of the internet: Complexity of flow dynamics in a packet switching network</i> (full article)	364
Takeshi Ishida. <i>Simulation of cell-like self-replication phenomenon in a two-dimensional hybrid-cellular automata model</i> (full article)	372
Daniel Jones and Tim Blackwell. <i>Social learning and evolution in a structured environment</i> (full article)	380
Yoshiaki Katada. <i>Evolutionary dynamics of GAs in a simple model with dynamical environment and neutrality</i> (full article)	388
Susan Khor. <i>Why aren't protein residue networks smaller worlds?</i> (full article)	397
Anaïs Khuong, Guy Theraulaz, Christian Jost, Andrea Perna and Jacques Gautrais. <i>A computational model of ant nest morphogenesis</i> (full article)	404
Joon Kim, Juyeol Yun, Jewoo Hong, Hyojung Kwon and Junghwa Chun. <i>Ecohydrologic and biogeochemical process networks in forest ecosystems in monsoon east asia: Identification and interpretation</i> (abstract)	412
Carole Knibbe, David P. Parsons and Guillaume Beslon. <i>Parsimonious modeling of scaling laws in genomes and transcriptomes</i> (abstract)	414
Davis Knox and John Rieffel. <i>Scalable co-evolution of soft robot properties and gaits</i> (full article)	416
Artemy Kolchinsky and Luis M. Rocha. <i>Prediction and modularity in dynamical systems</i> (full article)	423
Peter Kreyssig and Peter Dittrich. <i>Reaction flow artificial chemistries</i> (full article)	431
Yutetsu Kuruma, Toshiharu Suzuki, Masasuke Yoshida and Takuya Ueda. <i>Artificial organelle for energy production in artificial cell</i> (abstract)	438
Tüze Kuyucu, Ivan Tanev and Katsunori Shimohara. <i>Genetic transposition inspired incremental genetic programming for efficient coevolution of locomotion and sensing of simulated snake-like robot</i> (full article)	439
Sébastien Le Yaouanq, Pascal Redou, Christophe Le Gal, Jean-François Abgrall and Jacques Tisseau. <i>Multi-Agent systems and heterogeneous scales interactions. Application to pharmacokinetics of Vitamin K antagonists</i> (full article)	447
Shuguang Li, Jianping Yuan and Juan Cristóbal Zagal. <i>Encouraging networks modularity</i>	455

*by seeding motifs* (full article)

# Foreword

## ECAL'11: Back to the Origins of Alife

There is a long tradition of software simulations in theoretical biology to complement pure analytical mathematics, which are often limited in their ability to reproduce and understand self-organisation phenomena resulting from nonlinear and spatially grounded interactions of a huge number of various and evolving biological objects. Researchers in Artificial Life (Alife) bet that they can assist biologists in this domain, transcending their daily modelling and measuring practice by using software simulation in the first instance, and robotics, too, in order to abstract and elucidate the fundamental mechanisms common to living organisms. They hope to do so by discovering the most informative level of abstraction and resolutely neglecting a lot of physical and quantitative information deemed not indispensable. The computer is apparently the best microscope to achieve this. They want to focus on the rule-based mechanisms that make life possible, supposedly neutral with respect to their underlying material embodiment, and replicate them in a non-biochemical substrate. The hypothesis is that minimal life begins at the intersection of a series of processes that need to be isolated, differentiated and duplicated as such in computers, and that only software development and execution make possible to understand the way these processes are intimately interconnected in order for life to emerge at the crossroad.

The rejection of an authoritative definition of “life” is often compensated for by a list of functional properties that never finds unanimity amongst its authors. Some demand more properties, others require fewer of those properties that are often indicated in vague terms such as “self-maintenance”, “self-organisation”, “metabolism”, “autonomy”, “self-replication”, or “open-ended evolution”. A first determining role of Alife consists in writing and implementing software versions of these properties and the way they actually interact. The goal is to disambiguate them and make them algorithmically precise enough so that, in the end, the only remaining cause of disagreement on the definition of life would reside in the length or the composition of this list but not in its items.

Biologists obviously remain the most important partners; but what may they expect from this Alife business? What can they expect from these new “Merlin hackers”, whose ambitions seem, above all, disproportionately naïve. Computer platforms are useful and necessary in several ways. First of all, they open the door to a new style of teaching and advocating major biological ideas: in other words, computer software as a pedagogical tool. For example, Richard Dawkins is the best advocate of Darwinian ideas when running a computer simulation in which sophisticated creatures known as “biomorphs” evolve on a computer screen by means of a genetic algorithm. These same platforms and simulations can, insofar as they are sufficiently flexible, quantifiable and universal, be used more accurately by biologists, who will find in them a simplified way of simulating and validating a given biological system under study. Cellular automata, Boolean networks, genetic algorithms and algorithmic chemistry are excellent examples of softwares to download, parameterise and use to reproduce the required natural phenomenon. Their predictive

power varies from very qualitative (where results apparently reproduce general trends of the real world) to very quantitative (where numbers produced by the computer may be precise enough to be compared with those measured in the real world).

Although being at first very qualitative, precise and clear coding is already the guarantee of an advanced understanding accepted by all. Algorithmic writing is an essential stage in formalising the elements of the model and making them objective. The linguistic and qualitative style of many biological papers could benefit in clarity by attempting a software instantiation of their contents. The more the model allows to integrate what we know about the reality being reproduced, the detailed structure of the objects and the relationships between them, the more the predictions will move from qualitative to precise, and the more easily the model will be validated according to Karl Popper's "falsification" process of good scientific practice.

Ideally, through systematic software experiments, these platforms can lead to the discovery of new natural laws, whose impact will be all the greater as the simulated abstractions will be present in many biological realms. In the 1950's, when Alan Turing discovered that a simple diffusion phenomenon, propagating itself at different speeds, depending on whether it is subject to a negative or positive influence, produces zebra or alternating motifs, it had a considerable effect on a whole section of biology studying the genesis of forms. This was Alife at its best. The same happened with John von Neumann's self-replicating automata. Because of these seminal works, Turing and von Neumann remain the two spiritual fathers of the field. When scientists discovered that the number of attractors in a Boolean network (Kauffman) or a neural network (Hopfield) exhibited a given dependency on the number of units in these networks, these results could equally well apply to the number of cell types expressed as dynamic attractors in a genetic network or the quantity of information capable of being memorised in a neural network. Entire chapters of biology dedicated to networks (neural, genetic, protein, immune, hormonal) had to be re-written in the light of these discoveries. When other scientists recently observed non-uniform connectivity in many networks, whether social, technological or biological, showing a small number of hubs with a large number of connections and a greater number of nodes with far fewer, and when, in addition, they explained the way in which these networks are built in time by preferential attachment (Barabási), again biology was clearly affected.

Alife is of course at its best when it reveals new biological facts, destabilizing biologists' presuppositions or generating new knowledge, rather than simply illustrating or refining the old. Roughly said, we could construe Alife as being to theoretical biology what mathematics is to physics, that is, a more neutral scientific endeavour to provide open-minded biologists with new tools and new formal terms to describe and conceptualize the objects of their study. At the moment, the fact that this discipline is still young and shows relative immaturity in comparison with mainstream biology might explain why some observers remain skeptical in front of the current discrepancy between promises and reality. In our opinion, however, they tend to underestimate the importance of the results already obtained, as they are too riveted to their microscope. They should show less reluctance, indifference or even arrogance – and more

curiosity and conviviality – towards these new computer explorers who have set out on the conquest of life, just like them but in front of their computer screens.

This is how we saw Alife when Francisco Varela, Paul Bourguine and myself decided to organize the first European Conference on Artificial Life (ECAL) in Paris twenty years ago. We were very impressed by the Sante Fe workshops, which Chris Langton had started, and decided to initiate a European counterpart. We were aware of this very long tradition of theoretical biology in Europe, nevertheless a tradition still largely unaffected by the new opportunities offered by software simulations. We also realized that an opportunity existed to expand Alife “toward a practise of autonomous systems” with their “embodied cognition”, including not only all forms of life but also autonomous robots and collective intelligence. We emphasised the importance of developing artificial life toward new trends in theoretical biology, based on such practise of autonomous systems and not only on purely literary descriptions or purely mathematical formulations.

This opportunity exists more than ever for the future and we wanted to provoke discussions at ECAL about all major forms of autonomous systems, characterized by self-organized architectures, morphogenesis and adaptation, from minimal forms of life to the ecosphere, from minimal forms of cognition to human social intelligence, mediated through internet and the web. Besides, we did not want artificial life to become a sub-branch of engineering only weakly inspired by biology. In fact, other conferences already existed for that. ECAL ought to be different and unique, genuinely centred on theoretical biology and the physics of complex autonomous systems.

Today, although we are proud of this series of very successful and exciting ECAL conferences, we feel that the domain of Alife should look back to these origins and take even more inspiration from the new high-throughput developments at the intersection between computer science and theoretical biology. Closing a loop, this year’s ECAL will mark the 20th anniversary of the first ECAL and will be framed as a tribute to the late Francisco Varela. It was summer 1990, the three of us, with Paul Bourguine, were sitting in a café in Paris, drinking an excellent wine, when Francisco proposed to make our own version of an Alife conference. Thanks Francisco, we miss you.

Welcome to ECAL 2011!

Hugues Bersini

August 2011*

## Preface

ECAL, the European Conference on Artificial Life, is a biennial event that alternates with the US-based Alife conference series. In the early 1990's, the first two ECAL conferences in Paris and Brussels were mainly centered on theoretical biology and the physics of complex systems. After 20 years and 10 editions of this event, we felt that the domain should look back on these origins and our wish was to refocus the ECAL conference on complex biological systems.

Over the past two decades, biological knowledge has grown at an unprecedented rate, giving rise to new disciplines such as systems biology, testimony of the striking progress of modeling and quantitative methods across the field. During the same period, highly speculative ideas have matured, and entire conferences and journals are now devoted to them. Synthesizing artificial cells, simulating large-scale biological networks, storing and making intelligent use of an exponentially growing amount of data (e.g., microarrays), exploiting biological substrates for computation and control, and deploying bio-inspired engineering are all cutting-edge topics today.

ECAL'11 leveraged this remarkable development of biological modeling and extended the topics of Artificial Life to the fundamental properties of living organisms: their multiscale pattern-forming morphodynamics, their autopoiesis, robustness, capacity to self-repair, cognitive capacities, and co-adaptation at all levels, including ecological ones. Bringing together a large interdisciplinary community of biologists, computer scientists, physicists, and mathematicians, the conference gave them a moment to reflect on how traditional boundaries between disciplines have become blurred, and to revisit in depth what constitutes "life".

In order to make the event attractive to researchers from a wide range of disciplines, we decided to open the possibility to submit 2-page abstracts discussing work previously published by the authors in a journal. In addition to 148 full-length (8-page) articles reporting on new, unpublished work, we received 29 overview abstracts, for a total of 177 submissions.

Although intrinsically interdisciplinary, these submissions referred in particular to the main conference topics, as described by the histogram below. All submissions were subject to peer review. The work of our excellent Program Committee (see list of members below) allowed us to select 128 papers, subdivided into 72 oral presentations (for a 40.7% acceptance rate) and 56 posters (31.6%), with no distinction being made between the two submission options, full paper or abstract. Two accepted papers were later withdrawn by their authors, reducing the total number to 126 (72 + 54).

All papers were presented during the four days of the plenary conference, which was held at the Cité Internationale Universitaire de Paris, France from August 9 to 12, 2011. Oral and poster sessions alternated with six world-class keynote speakers, whose invited contributions (abstracts or full papers) are also published in the front section of these proceedings: Jacques Demongeot, David Harel, James D. Murray, Jordan Pollack, Ricard Solé, and Eric Wieschaus (see their biosketches below). We thank them for taking the time and effort to participate in the conference.

## Satellite Workshops

In addition to the plenary conference, we were also pleased to give Alife researchers the opportunity to organize satellite workshops and tutorials in two “bookend” sessions, on the first day (August 8) and last afternoon (August 12). These special sessions were dedicated to the same [general topics](#) as the main conference, while allowing for more focused interactions among participants. They were independently managed by their organizers and could comprise any combination of peer-reviewed papers, posters, invited talks, panel discussions, etc. Workshop contributions were not included in these proceedings. We received 15 proposals, of which 14 effectively took place, testimony of the liveliness of the field:

- *AAALE: Alife Approaches to Artificial Language Evolution*  
Luc Steels and Tony Belpaeme
- *ACCS: Artificial Chemical Computing Systems*  
Hideaki Suzuki and Hiroki Sayama
- *BioChemIT: 1st COBRA Workshop on Biological and Chemical Information Technologies*  
Peter Dittrich, Zarka Khan and Martyn Amos

- *CoSMoS: 4th Workshop on Complex Systems Modelling and Simulation*  
Paul Andrews, Susan Stepney, Peter Welch and Carl Ritson
- *CS-Sports: Complex Systems in Sports*  
Juan Julián Merelo Guervós, Antonio Mora García and Carlos Cotta Porras
- *DDLab: Exploring Discrete Dynamics: From Cellular Automata to Random Networks*  
Andy Wuensche, Andy Adamatzky and Genaro Juárez Martínez
- *iBioMath: First International Workshop on Integral Biomathics*  
Plamen Simeonov, Andrée Ehresmann and Leslie Smith
- *INCUP: Information Coding in Unconventional Computing Substrates*  
Jerzy Gorecki and Andy Adamatzky
- *MASmms: Workshop on Multi-Agent Systems in Biology at meso or macroscopic scales*  
Pascal Ballet, Marie Beurton-Aimar, Guillaume Hutzler and Bertrand Laforge
- *MEW: 3rd Morphogenetic Engineering Workshop*  
René Doursat and Hiroki Sayama
- *RUTSAC: Research Using The Stringmol Artificial Chemistry*  
Simon Hickinbotham, Ed Clark and Adam Nellis
- *SIM-A: System Immunology Models of Autopoiesis*  
Uri Hershberg and Sol Efroni
- *SynBioCCC: Workshop on the Design, Simulation, Construction and Testing of Synthetic Gene Regulatory Networks for Computation, Control and Communications*  
Nawwaf Kharma and Taras Kowaliw
- *WAAT: Workshop on Artificial Autonomy: 20 years of practice of autonomous systems*  
Tom Froese, Matthew Egbert and Xabier Barandiaran

## Keynote Speakers

- **Jacques Demongeot** is presently director of the TIMC-IMAG Laboratory, “Techniques of Medical Engineering & Complexity” (CNRS 5525) and is also head of the Institute of Bioengineering (IFRT 130 IpV) at the University Joseph Fourier, Grenoble, France. He has an MD and a PhD in mathematics and has been appointed Chairman of Biomathematics at the Institut Universitaire de France in 1994. Jacques Demongeot is also in charge of the Department of Medical Information at the University Hospital of Grenoble (CHUG) and is the founder of the doctoral school of bioengineering “Health, Cognition & Environment”. He is currently creating a new laboratory AGIM, in Archamps near Geneva, devoted to studies of development and ageing.
- **David Harel** is a professor of computer science at the Weizmann Institute of Science in Israel. Harel is best known for his work on dynamic logic, computability and software engineering. In the 1980s he invented the graphical language of Statecharts, which has been adopted as part of the UML standard. He has also published expository accounts of computer science, such as his award winning 1987 book “Algorithmics: The Spirit of Computing” and has made appearances on Israeli

radio and television. He currently works on many diverse topics, including visual languages, graph layout, systems biology and the communication of odours. He is now working on a computer model of a nematode, ‘*Caenorhabditis elegans*’, which was the first multicellular organism to have its genome completely sequenced. The eventual completeness of such a model depends on his updated version of the test developed by Alan Turing to identify whether computers could reason well enough that a human communicating with them could not tell whether a human or a machine was at the other end of the communication.

- **James D. Murray**, FRS, Foreign Member of the French Academy, is Professor Emeritus of Mathematical Biology at the University of Oxford, Professor Emeritus of Applied Mathematics at the University of Washington, and Senior Scholar at Princeton University. His research is characterized by its great scope and depth: an early example is his fundamental contributions to understanding the biomechanics of the human body when launched from an aircraft in an ejection seat. He has made contributions to many other areas, ranging from understanding and preventing severe scarring, to fingerprint formation, sex determination, modeling of animal coat patterns, territory formation in wolf-deer interacting populations, growth and control of brain tumors, quantifying patient treatments prior to use, and modeling marital interaction and divorce prediction with 94% accuracy in a 12-year longitudinal study. He is best known for his authoritative and extensive work entitled *Mathematical Biology*, whose 3rd edition in two volumes came out in 2004.
- **Jordan Pollack** is professor of computer science and complex systems professor at Brandeis University, where he is also chairman of the computer science department and director of the Dynamical and Evolutionary Machine Organization (DEMO) lab. The laboratory’s work on AI, Artificial Life, Neural Networks, Evolution, Dynamical Systems, Games, Self-designed Robotics, Machine Learning, and Educational Technology has been reported on by the New York Times, Time, Science, NPR, Slashdot.org and many other media sources worldwide.
- **Ricard Solé** heads the Complex Systems Lab at Universitat Pompeu Fabra, Barcelona, and is an External Professor at the Santa Fe Institute. One of his main research interests is understanding the possible presence of universal patterns of organization in complex systems, from prebiotic replicators to evolved artificial objects. Key questions are how robust structures develop, how information is incorporated into these structures and how computation emerges. He is also interested in how to determine what are the contributions of selection, chance and self-organization to the evolution of complexity. One of his main goals is searching for the principles of organization responsible for the emergence of fundamental components of complexity, including the origins of self-reproduction, development, life cycles, computational processes and multicellularity. His work has been featured in newspapers as well as several popular and technical books.
- **Eric Wieschaus** is the Squibb Professor in Molecular Biology at Princeton. His research work has focused on embryogenesis in the fruit fly *Drosophila melanogaster*, specifically in the patterning that occurs in the early *Drosophila* embryo. Most of the gene products used by the embryo at these stages are already present in the unfertilized egg and were produced by maternal transcription during oogenesis. A small number of gene products, however, are supplied by transcription in the embryo itself. He has focused on these “zygotically” active genes because he believes the temporal and spatial pattern of their transcription may provide the triggers controlling the normal sequence of embryonic development. In 1995, he was awarded the Nobel Prize in Physiology or Medicine with Edward B. Lewis and Christiane Nüsslein-Volhard as co-recipients, for their work revealing the genetic control of embryonic development.

## Alife Pioneers Panel Discussion

In addition to an exceptional selection of keynote speakers, an exciting panel discussion involving several internationally renowned pioneers of Artificial Life took place at the end of the second day of the plenary conference. Mark Bedau, Takashi Ikegami, Stuart Kauffman, Norman Packard, Steen Rasmussen, Luc Steels, and Susan Stepney all talked about the most impressive achievements of Alife in the past, since inception of the field, and pointed to what they thought were the most promising research directions for the future. Some of them also provided an invited contribution (abstract or full paper), which can be found in the same section as the keynotes' contributions.

- **Mark Bedau** (Reed College, Portland – European School of Molecular Medicine, Milan – Initiative for Science, Society, and Policy, Denmark) pioneered the field of quantifying and comparing the evolutionary activity in artificial and natural systems, and is an international leader in the evolutionary design of complex biochemical systems using statistical models and prediction algorithms. Because he combines training in analytical philosophy with over a decade of experience in artificial life, he is recognized as a uniquely qualified expert in the philosophical foundations of complex adaptive systems. Mark Bedau is Editor-in-Chief of the international journal *Artificial Life* (published by MIT Press), he co-organized five international conference on artificial life, co-founded a start-up company, ProtoLife SRL, and co-founded the European Center for Living Technology, a research institute in Venice, Italy, that investigates theoretical and practical issues associated with living systems.
- **Takashi Ikegami** is a professor at the Department of General Systems Sciences of the Graduate School of Arts and Sciences, University of Tokyo, where he specializes in complex systems and artificial life. Takashi takes a computational/philosophical approach to designing artificial life, exploring issues at the margins of his discipline. He is also an arts collaborator with Keichiro Shibuya (ATAK) on making three-dimensional sound installations. Keywords: chemical computing, smart chemical agents, chemotaxis, living technology, artificial life, first cell.
- **Stuart Kauffman** (University of Vermont, Burlington) is an American theoretical biologist and complex systems researcher concerned with the origin of life on Earth. He is best known for arguing that the complexity of biological systems and organisms might result as much from self-organization and far-from-equilibrium dynamics as from Darwinian natural selection, as well as for applying models of Boolean networks to genetic circuits. Stuart Kauffman rose to prominence through his association with the Santa Fe Institute, where he was faculty in residence (1986-1997), and his work on models in various areas of biology. These included autocatalytic sets in origin of life research, gene regulatory networks in developmental biology, and fitness landscapes in evolutionary biology. Stuart Kauffman held a joint appointment at the University of Calgary in Biological Sciences and Physics and Astronomy (2005-2009), then joined in 2010 the University of Vermont where he will continue his work with UVM's Complex Systems Center.
- **Barry McMullin's** primary research activity at the Rince Research Institute, Dublin City University (DCU), is in the domain of Artificial Life. He serves on the organizing committees of both ECAL and Alife conferences, and as a member of the Editorial board of the *Artificial Life* journal. He has a secondary research interest in the area of Web Accessibility, engineering web sites and services to best meet the requirements of all users, specifically including those with disabilities. Between 1999 and 2004, Barry McMullin was the first DCU Dean of Teaching and Learning. In this role he was responsible for the development of a wide series of initiatives to significantly enhance the quality of the student learning experience at DCU. Barry McMullin was

appointed to the rank of Associate professor at DCU in September 2010, and became Director of RINCE, a national research institute specializing in Engineering technology innovation, in February 2010.

- **Norman Packard** (European Center for Living Technology, Venice) has worked in the areas of chaos, learning algorithms, predictive modeling of complex time series, statistical analysis of evolution, artificial life, and complex adaptive systems. He was co-founder of Prediction Company in 1991 and served as its CEO (1997-2003) and chairman until 2005. Norman Packard is currently working in a new scientific and business direction based on development of evolutionary chemistry in programmable microfluidic technology. Long-range applications of this technology include the fabrication artificial cells from non-living material, and their programming for useful functionality. In 2004, Norman Packard was co-founder of ProtoLife S.r.l. (Venice, Italy), which applies machine learning techniques to the design of experiments (DoE) for high throughput experiments in biotechnology. As part of the PACE project (Programmable Artificial Cell Evolution, 2004-2008), he also participated in the founding of ECLT, the European Center for Living Technology.
- **Steen Rasmussen** is currently the Head of the Center for Fundamental Living Technology (FLinT), a Research Director at the Department for Physics and Chemistry at University of Southern Denmark, Odense, and External Research Professor at the Santa Fe Institute. He has pioneered approaches, methods, and applications for self-organizing processes in natural and artificial systems: abstract self-programmable matter, molecular dynamics (MD) lattice gas simulations for molecular self-assembly, rational and evolutionary protocell design, disaster mitigation and decision support systems based on collective intelligence, as well as novel simulations for large-scale sociotechnical systems. Steen Rasmussen was heading the Protocell Assembly (LDRD-DR) project and the Astrobiology program (origins of life) at Los Alamos, developing experimental and computational protocells and cell-like entities. He also co-directed the European PACE project (Programmable Artificial Cell Evolution) project.
- **Luc Steels** is professor of Computer Science (at the moment part-time) at the Free University of Brussels (VUB), founder and director (since 1983) of the VUB Artificial Intelligence Laboratory and co-founder and chairman (1990-1995) of the VUB Computer Science Department. He has also been the director of Sony CSL in Paris since its creation in 1996. His scientific research interests cover the whole field of artificial intelligence, including natural language, vision, robot behavior, learning, cognitive architecture, and knowledge representation. At the moment his focus is on dialogs for humanoid robots and fundamental research into the origins of language and meaning. Current work focuses on developing the foundations of semiotic dynamics and on fluid construction grammars.
- **Susan Stepney** leads the Non-Standard Computation research group, and is one of the instigators of the new interdisciplinary York Centre for Complex Systems Analysis, University of York. Originally a theoretical astrophysicist, she has spent the bulk of her professional career in industrial R&D (GEC-Marconi and Logica), mostly in mathematical and computational modelling, researching aspects of novel computation. She is a moderator of the UKCRC Grand Challenge 7 in Non-Classical Computation and is helping to build a conceptual meta-framework for bio-inspired computation. Current research interests also include theories of emergence and self-organising systems, and nature-inspired computational metaphors. She is the PI of the Complex Systems Modelling and Simulation project and was PI of the EIVIS novel computation cluster, rated “outstanding”. She also teaches complex biosystems simulation and is responsible for designing the new Masters course in Natural Computation at York.

## Alife Art Exhibit and Performance

Inspiration, imagination and aesthetics are an integral part of science, and they are of particular importance in the Alife community, which fuels some of the most creative and provocative research at the edge (of chaos) between biology and technology. Accordingly, ECAL'11 welcomed a prominent visual artist, Louis Bec, and a distinguished musician, François Pachet, who showcased their exciting work in the exhibit rooms and main auditorium.

- **Louis Bec**, born in Algeria and living in France, is a biologist and zoosystematician who extends his scientific field with a fabulatory epistemology based on Artificial Life and Technozoosemiotics. In 1972, Bec founded the Institut Scientifique de Recherche Paranaturaliste, where he studies the incapability of living beings to understand their own existence. Bec is both artist and scientist in the field of artificial life and 3D technologies. He is as much a biologist, artist, curator and educator, and has been a ministry officer for new technologies in arts. Bec is Director of CYPRES (Centre Interculturel de Pratiques et Echanges Transdisciplinaires) in Marseille. He has presented his ideas in many exhibitions, such as Alife II (invited by Chris Langton) and *From Animals to Animats*, and articles.
  - ***Upokrinomenes: a fabulated epistemology*** Zoosystemician Louis Bec forces us to question the validity of each claim by reformulating and staging scientific discourse. His reasoning possesses all the marks of scientific assertiveness, combining scientific jargon with scholarly neologisms. Questioning life and our inability to understand it through traditional investigative methods, he founded the field of *Upokrinomenology*. It is a theory of life using models based on computer science, robotics, video and other interactive devices, where irony holds a significant place. By putting scientific discourse into perspective, he challenges us to investigate, unravel and interpret the propositions that he makes. In this research, scientific discourse becomes poetic and Louis Bec becomes a storyteller. Founder of the Scientific Institute of Paranaturalistic Research, he invites us to discover a life we did not know existed, one that looms at the border between shapes, language and behavior [after C. Beaugrand & A. Charre, *Reinventing the museum*]. (Art exhibit at ECAL'11 designed and installed with François Mourre, Patrice Bersani and Delphine Fabbri-Lawson.)
- **François Pachet** is a Civil Engineer (Ecole des Ponts and Chaussées) and was an Assistant Professor in Artificial Intelligence and Computer Science, University of Paris 6, until 1997. He then set up the music research team at the Sony Computer Science Laboratories, Paris, and developed the vision that metadata can greatly enhance the musical experience in all its dimensions, from listening to performance. His team conducts research in interactive music listening and performance and musical metadata and developed several innovative technologies and award winning systems (MusicSpace, constraint-based spatialization, PathBuilder, intelligent music scheduling using metadata, The Continuator for Interactive Music Improvization). He is the author of over 80 scientific publications in the fields of musical metadata and interactive instruments.
  - ***The Continuator Project: playing with virtual musicians*** François Pachet (guitar player) and Jeff Suzda (professional sax player) performed a short Jazz concert with their band “Quintet of Two”. They comprised the two human musicians in the group, performing alongside three “software” musicians. The goal of this project was to play “standard” jazz using virtual instruments intimately controlled by the human players. The technologies employed, developed at Sony CSL, involve Markov chains, constraint programming, signal processing, and a great degree of musical tuning. Performance was still exploratory, but the goal is to enhance musical expressivity through controllable machines.

## Program Committee

An event like ECAL'11 would not have been possible without the following dedicated members of the Program Committee and additional reviewers. Our gratitude goes to all of them.

Hussein Abbass	Joachim De Beule	Pedro U. Lima	Matthias Scheutz
Andy Adamatzky	Bart De Boer	Daniel Lobo	Thomas Schmickl
Chris Adami	Ralf Der	Fernando Lobo	Marc Schoenauer

## Organizing Committee

- René Doursat (General Chair) *Complex Systems Institute, Paris Ile-de-France, CNRS – CREA, Ecole Polytechnique & CNRS, Paris*
- Hugues Bersini (Co-Founder) *IRIDIA, Université Libre de Bruxelles*
- Paul Bourguine (Co-Founder) *Complex Systems Institute, Paris Ile-de-France, CNRS – CREA, Ecole Polytechnique & CNRS, Paris*
- Tom Lenaerts (Program Chair) *MLG, Université Libre de Bruxelles – AI-lab, Vrije Universiteit Brussel*
- Mario Giacobini (Program Chair) *Dept. of Animal Productions, Epidemiology and Ecology – Molecular Biotechnology Center, University of Torino*
- Marco Dorigo (Co-Organizer) *IRIDIA, Université Libre de Bruxelles*

## Administrative and Onsite Staff

Finally, we want to thank for their invaluable help all those who were involved in the preparation of the event, in particular

- Marcel Skrobek (office head)
- Stéphanie Bayou-Zaba (assistant)
- Geneviève Tual (office manager)
- Razvan Dordea (MSc student) *Complex Systems Institute, Paris Ile-de-France, CNRS – CREA, Ecole Polytechnique & CNRS, Paris*
- Muriel Decreton (office manager)
- Eliseo Ferrante (PhD student)
- Vito Trianni (postdoc) *IRIDIA, Université Libre de Bruxelles*
- Manuele Brambilla (PhD student)
- Alessandro Stranieri (PhD student)
- Matthew Egbert (research fellow) *University of Sussex*
- Luca Ferreri (PhD student) *University of Torino*
- Regina Frei (postdoc) *Imperial College London*
- Carlos Quintana (PhD student) *University of Malaga*
- Gabriel Varela (student) *Bowdoin College, Brunswick, Maine*

## Art Exhibit: Graphic & Electronic Engineers, Set Designers

- François Murre (founder) *3D from Mars*
- Patrice Bersani (CEO) *DreamLabs*
- Delphine Fabbri-Lawson (art curator)

## Support

We are also very grateful to the following institutions for their financial support:

- Complex Systems Institute, Paris Ile-de-France, itself sponsored by the Région Ile-de-France
- CREA, Ecole Polytechnique & CNRS, Paris
- IRIDIA, Université Libre de Bruxelles
- Fondation Jean-Marie Delwart, Bruxelles

The organizing committee of ECAL'11:

René Doursat, Hugues Bersini, Paul Bourguine,

Jacques.Demongeot@agim.eu

## Abstract

The general architecture of a genetic regulatory network consists of strong connected components of its interaction graph, to which are attached three kinds of sub-structures:

- a set of up-trees, rooted in the sources of the interaction graph, represented either by small RNAs like microRNAs: nuclear miRs or mitochondrial mitomiRs, i.e., translational inhibitors respectively of the messenger mRNAs and of the transfer tRNAs, or by gene repressors and/or inducers,
- a set of circuits in the core (in graph sense) of the strong connected components of the interaction graph,
- a set of down-trees going to the sinks of the interaction graph, i.e., to genes controlled, but not controlling any other gene.

The various state configurations it is possible to observe in the above sub-structures correspond to different dynamical asymptotic behaviors. The network dynamics have in general a small number of attractors, corresponding in the Delbrück's paradigm to the functions of the tissue they represent. Examples of such dynamics will be given in embryology: cell proliferation control network in mammals and gastrulation control network in *Drosophila melanogaster*.

## Introduction

Genetic networks can be considered as the analogues of neural networks for controlling the expression of genes. Their time constants are different (e.g., the rhythms of protein expression are of the order of magnitude of some minutes and those of neural firing are of some milliseconds) but their connectivity is about the same (in-degree between 1.5 and 3, i.e., the mean number of the genes or neurons influencing positively or negatively other ones is between 1.5 and 3) as well as the number of their strong connected components (rarely more than 2 for the control of a dedicated function). For these reasons, many common mathematical features have been adopted by the modelers in charge of designing the interaction graph of such networks: i) Boolean representation of the state space (1 if the gene is expressed, 0 if not), ii) Hopfield-like transition function (Demongeot and Sené, 2008d; Demongeot et al., 2008c, 2009b, 2011b, in press) and iii) extraction of the same features, like entropy and motifs (Demongeot et al., 2010). We will use in this paper this common theoretical framework in order to interpret examples of the genetic network dynamics.

## Generalities about the architecture of the interaction graph of a genetic network

Figure 1: The interaction graph (top left) and the trajectory graph of a Boolean genetic regulatory network

The architecture of a genetic network can be decomposed into 3 directed graphs: i) the interaction graph with positive (resp. negative) arrows for induction (resp. repression), ii) the trajectory graph made of the consecutive states from an initial state until an asymptotic behavior (fixed state or limit-cycle of periodic states) and iii) the updating graph with an arrow between two genes if the target gene is updated after the source one. The knowledge about the first graph is given by DNA-protein interactions, about the second by DNA array devices recording gene expression and about the third by the chromatin clock. This architecture shows in Figures 2 and 3 some common features: i) a set of up-trees, issued from the sources of the interaction graph of the network, made either of small RNAs like siRNAs or microRNAs (nuclear miRs or mitochondrial mitomiRs, respectively translational inhibitors of the messenger mRNAs and of the transfer tRNAs), or of gene repressors and/or inducers, self-expressed without any

other gene controlling them, ii) a set of circuits in the core (in the graph sense) of the strong connected components of the interaction graph. These circuits are unique or multiple, disjoint or intersected, reduced to one gene or made of several ones, negative (having an odd number of negative interactions) or positive, and iii) a set of down-trees going to the sinks of the interaction graph.

By identifying each function of a regulatory network to one of the attractor of its dynamics as suggested by Delbrück (Demongeot, 1998), it is possible to count the number of the attractors provided by isolated circuits, and the number – largely reduced – brought by tangential or intersected circuits (Demongeot et al., 2009b, 2011a, 2011b, in press), depending on the updating mode fixed by the chromatin dynamics.

### The control of the genetic networks by microRNAs (miRs). Example of mitomiRs

Since a decade, numerous small RNAs issued from the non coding part of plant and animal genomes (like silencing siRNAs and microRNAs or miRs) have been found as inhibiting the translation by hybridizing the mRNAs with the help of RNA-binding oligo-peptides. This inhibition is partly aspecific because of the large number of possible mRNA targets for each small RNA. On Figure 2, the dynamics of a circuit of size 3 (3-circuit) is analyzed, when one gene of the 3-circuit is inhibited by a miR. If the inhibition is associated to another inhibition of this gene or if it is sufficiently strong, it is able to transform a limit-cycle behavior in a fixed configuration, the circuit being either negative or positive (Figure 2 top left and top middle). When the miR inhibition is less than the activation on the target gene, then the periodic behavior is conserved (Figure 2 top right). We can say that the inhibitory influence by the small RNAs is exerted only on sufficiently “weak” circuits, like on the carved (weak) zones of an etching on which only the nitric acid can carve.

Recently some nuclear miRs like miR-1977 (Figure 3) have been discovered whose targets are mitochondrial mRNAs coding for enzymes of the oxidative phosphorylation (Bandiera et al., 2011). Such miRs have been called mitomiRs (Dass et al., 2010). This discovery invited to examine if there exist parts of the non-coding mitochondrial DNA (called the d-loop, cf. Figure 3) susceptible to code for hybridizing RNAs blocking the free parts (the loops) of the mitochondrial tRNAs: the corresponding inhibition would be totally aspecific and exerted in situ without nuclear control in order to slow oxidative phosphorylation in absence of a strong energetic need. This effect could be useful for ruling the balance Pasteur/Warburg effect versus OxPhos effect, allowing to avoid both cancers in case of Pasteur/Warburg dominance and degenerative diseases in case of oxidative phosphorylation dominance (Demetrius et al., 2010; Israel and Schwartz, 2011).

Several sequences corresponding to the tRNA loops – essentially the tRNA D-loop, but also Anticodon-loop and TψC-loop have been found both in nuclear and in mitochondrial miRs. We will take in the following as reference the Lewin’s tRNA given in (Krebs et al., 2009): it

has been proved that the loops sequence in this reference tRNA was the closest among all known tRNAs to an Archetypal Basic RNA sequence of 22 bases (called RNA AB) verifying the following variational min-max principle:

- to be as short as possible,
- to present one and only one triplet corresponding to each amino-acid, in order to serve as “matrimonial agency” favouring the vicinity of any couple of amino-acids, close to RNA AB, and able to form strong peptide bonds (i.e., covalent chemical bonds formed by two amino-acids, when the carboxyl group of one reacts with the amine group of the other) between them, in order to initiate the peptide building as an ancestral tRNA, well conserved for example in the present Gly-tRNA of *Oenothera lamarckiana*.

For satisfying the constraints above, the RNA AB must be circular and contain at least 20 triplets. The minimal solution is given in (Demongeot and Besson, 1983; Demongeot and Moreira 2007; Demongeot et al. 2006, 2008a, 2009a, 2009c). The corresponding RNA AB sequence can be given in circular or hair-pin form and could be considered as the ancestor of the present tRNA loops. We will indicate in the following in blue the possible hybridization sites, by using the complementary pairing A-U, C-G and G-U:

1) for the nuclear mitomiRs, we have a pairing with:

- the D-loop and TψC-loop (13/22) (Bandiera et al., 2011)

**5' UAAAUUGGUACUGCCAUAAGA 3' AB**

**3' AAUUGUCGAUUCGUGGGAUUAG 5' miR 1977**

- the Anticodon-loop (12/22) (Bandiera et al., 2011)

**5' UUCAAGAUAAAUGGUACUGCCA 3' AB**

**3' AUAAGAGCGUGCCUGAUGUUGGU 5' miR 1974**

- the TψC-loop (12/22) (Bandiera et al., 2011)

**5' GAUAAAUGGUACUGCCAUAUAA 3' AB**

**3' AUCUUCCGAUCCUGGUUUGG 5' miR 1978**

2) for the mitochondrial mitomiRs, we have a pairing with:

- the D-loop (Cui et al., 2007)

the sequence **AAUGGUA** is found in many species in the CSB part of the mitochondrial d-loop (Figure 3)

- the TψC-loop (Sbisa et al., 1997)

the sequence **GUACAUU** is found in many species in the ETAS part of the mitochondrial d-loop (Figure 3)

Each pairing described above corresponds to a probability less than  $10^{-4}$  to occur (Demongeot and Moreira, 2007) and could correspond to the relics of an ancient protein building mechanism without ribosomes, in which the amino-acids were directly linked to RNA chains or cycles playing the role of matrimonial agency, i.e., facilitating the grouping of amino-acids, hence favoring the constitution of peptidic bonds between them (for other hypotheses concerning the catalysis of peptidic synthesis, see (Huber and Wächtershäuser, 1998; Hsiao et al., 2009)). When tRNA loops are hybridized by nuclear or mitochondrial mitomiRs, efficacy and specificity of the complex made of amino-acid, tRNA and amino-acyl-synthetase (enzyme esterifying an amino-acid for complexing it to a specific tRNA) can be affected, causing an inhibition of the translation mechanism.

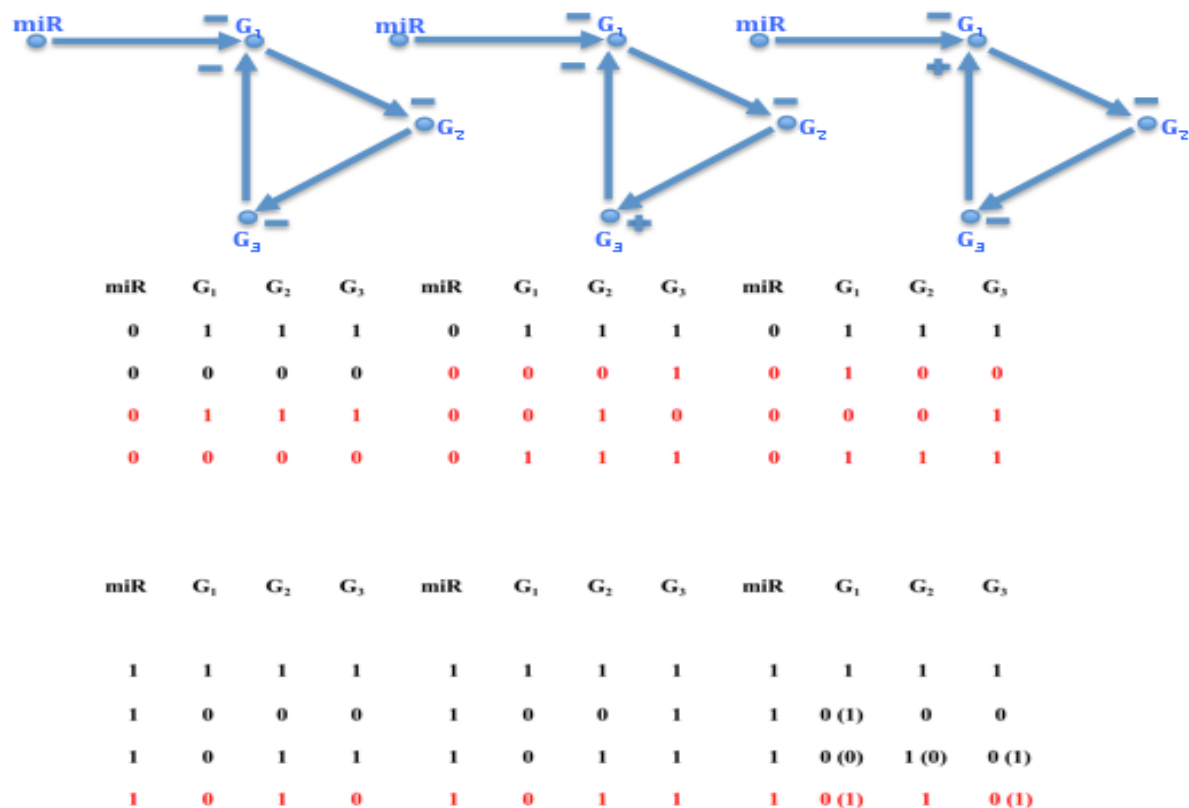

Figure 2: Top) Architecture of 3-circuits controlled by a miR, with negative (left) and positive (middle and right) circuits. Middle) Periodic dynamics when the miR is not expressed (miR=0). Bottom) Fixed configuration if the miR is expressed (miR=1), except if the miR inhibition is less than the gene activation (in parentheses), case in which the periodic behavior is conserved.

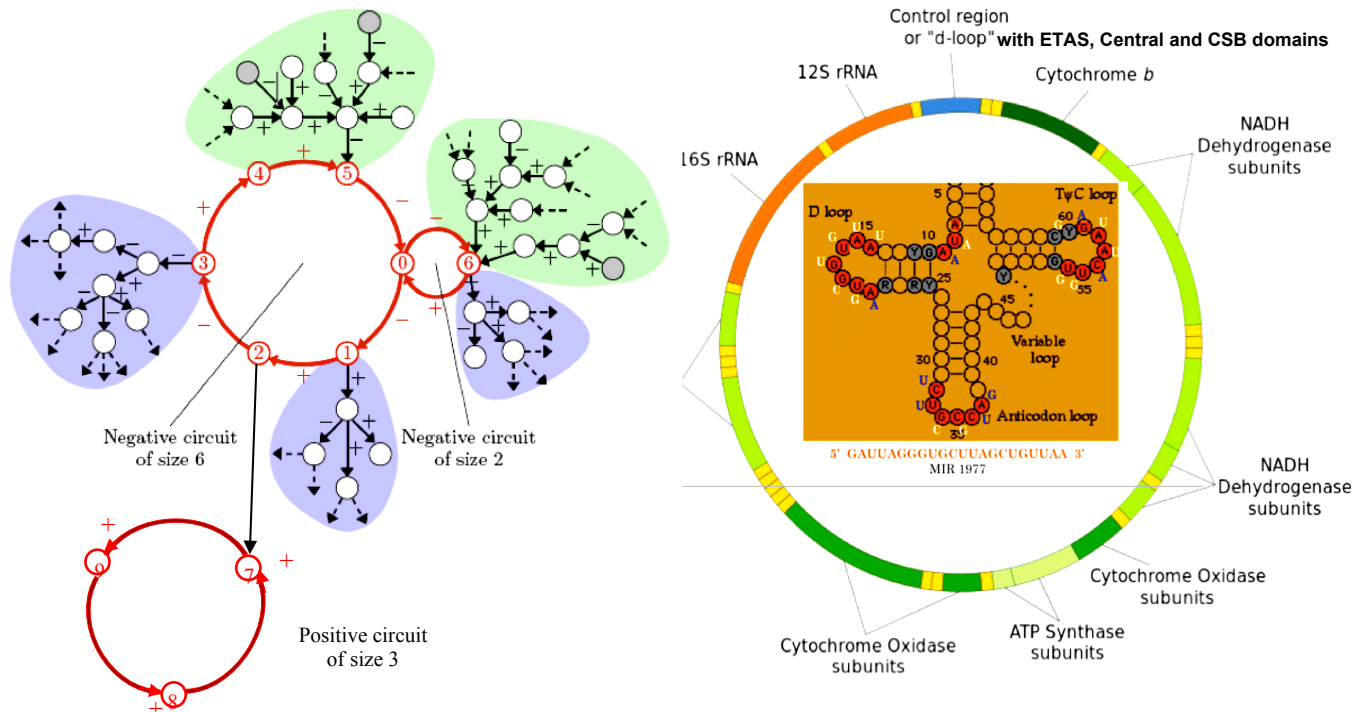

Figure 3: Left) General architecture of a genetic network with 2 circuit layers (red), 2 up-trees (green) and 3 down-trees (violet). Right) the circular mitochondrial DNA with its non-coding part (d-loop blue) and inside a tRNA structure hybridized by miR 1977.

# Genetic network ruling the cell-cycle

The genetic network ruling the cell-cycle in mammals, centered on the gene E2F, is crucial for cells because of its links with Engrailed network controlling: i) through gene Elk

the potassium channels in hippocampus neurons ruling the memory (Top of the Figure 4) and ii) through genes Engrailed/GATA-6, c-Myc and RAS, in a double incoherent control pathway (with both positive and negative arrows, respectively in red and green in Figure 4), the apoptosis and proliferation processes. This last control must be very precise if the tissue controlled has to keep constant its cell number. A way to obtain this acute control is to intersect in the Engrailed network several circuits (cf. Figure 4 Bottom right and (Demongeot et al., 2009b, 2011a, 2011b, in press)) and to exert an inhibitory control through miRs and/or mitomiRs, themselves possibly controlled by p53 (Figure 4 Middle).

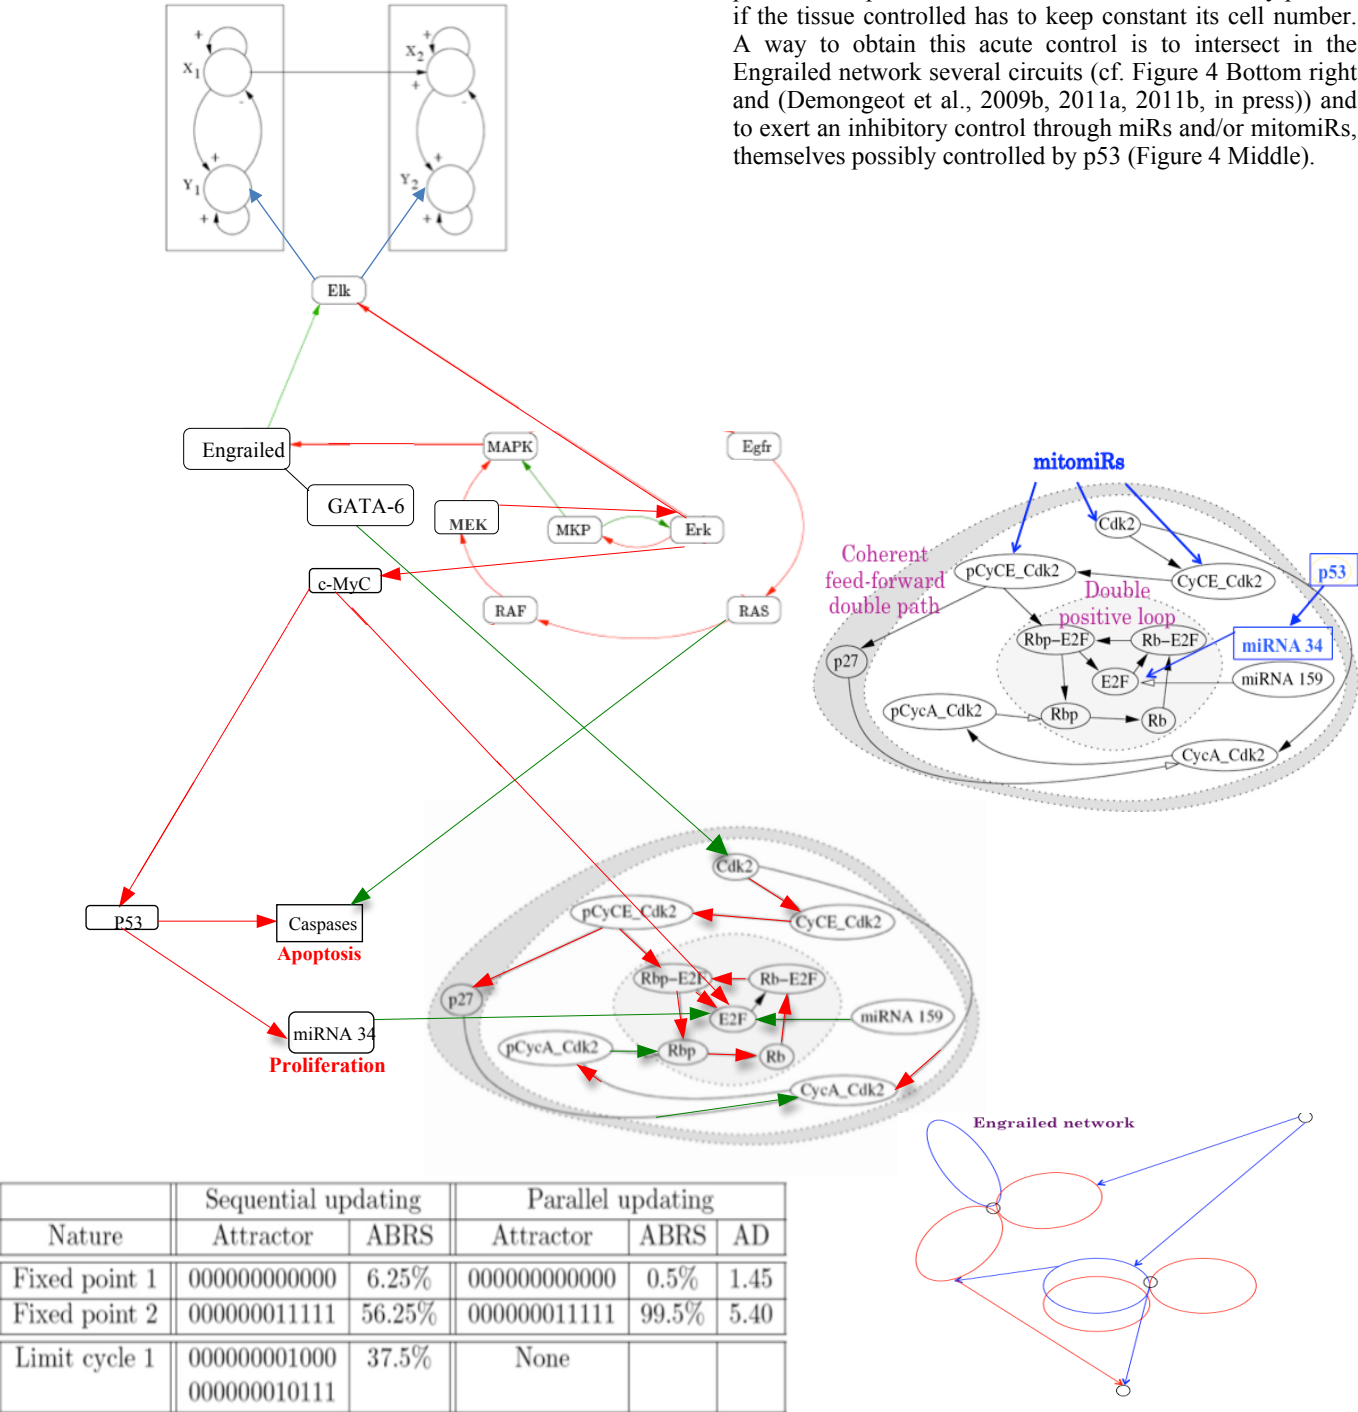

Figure 4: Middle right) Cell cycle controlling genetic network centered in mammals on the E2F box inhibited by small RNAs (miRs or nuclear and/or mitochondrial mitomiRs). Top left) Engrailed network controlling the potassium channels of hippocampus neural networks. Middle left) Engrailed network controlling both apoptosis and proliferation processes. Bottom left) Attractors of the dynamics specific to the E2F box. Bottom right) General structure of the Engrailed network.

Figure 5: Bottom left) Gastrulation controlling genetic network from (Leptin, 1999) with addition of 2 ATP and GTP controlling enzymes b and c. Top middle) Myosin controlling subnetwork. Bottom right) The 4 differentiated cells needed for building the future digestive tube.

A triple action (accelerate, stop and slow down the cell cycle) on proliferation process is exerted negatively by the gene GATA-6 which is inhibited 1 time out of 2 by MAPK, and successively positively and negatively by the gene c-MyC which is activated 1 time out of 2 by Erk. The limit cycle of order 4 brought by the negative circuit of size 2 (MKP/Erk) leads genes MKP, Erk, MAPK, Engrailed, GATA-6, c-MyC, p53, miRNA34, Cdk2, E2F and caspases to the limit-cycle: 01100001001, 11110100001, 10011110000, 00000011011. Then the second fixed point of the E2F box is reached 1 time out of 4 and the caspases/apoptose box is activated 1 time out of 2: this result allows the exponential growth of the cell number to be compensated in a tissue by the linear growth of the apoptosis, 2 daughter cells replacing 2 dead cells during one period of the limit cycle, hence ensuring the conservation of the tissue volume and tissue function, any disequilibrium of the balance giving either a tumor growth or tissue rarefaction.

### Genetic network ruling the gastrulation

The gastrulation is a dynamical process occurring at the end of the blastula phase. It is an early embryonic stage, including mass movement of cells to form complex structures from a simple starting form. Experiments in vivo have shown that there are many types of mass cell movement taking place during gastrulation: ingression, invagination, involution, epiboly, intercalation and convergent extension. In the next Section, we will focus on the simulation of the phenomenon of invagination of cells, which leads to the creation of the ventral furrow. In order to control the gastrulation process, a genetic regulatory network has been proposed in (Leptin, 1999). This network has been improved by adding 2 genes

(Figure 5 Bottom left): ATPase (enzyme located inside the inner mitochondrial membrane ensuring the resourcing of ATP from ADP) and DiNucleotide Phosphate Kinase (enzyme resourcing GTP from GDP and ATP). This addition of genes allows the network to pass from 2 to 4 attractors, providing the 4 types of differentiated cells (from bottle cell to intestinal epithelial cell) needed to achieve and finish the digestive tube (Figure 5 Bottom right). The CyT node correspond to the genes involved in the CyToskeleton formation, i.e., essentially the genes of Actin, Tubulin and Myosin, the latter being controlled by a specific subnetwork (Figure 5 Top middle). When the genes coding for the two types of Myosin (RLC, with Regulatory Light Chain and HC, with Heavy Chain) are expressed, then the ventral furrow invagination can start. We will model this process in the next Section showing with a simple mechanical model that it begins by a cell contraction followed by an invagination at the two extremities of the Drosophila embryo, extended after to central embryo region.

### Physical Model of Ventral Furrow

Several successful models have already been created in order to simulate the process of ventral furrow invagination in *Drosophila melanogaster*. Although they have been extensively monitored, the parameters driving the movement and deformation of cells are not fully explained. We shall describe the structure of our physical model, the parameters we used to create it, the assumptions we made and the new possibilities and questions raised by this approach. This work focuses on the area of the structure where the phenomenon begins. As a result, we have modelled the upper part of one side of blastula (Figure 6) as described in (Abbas et al., 2009).

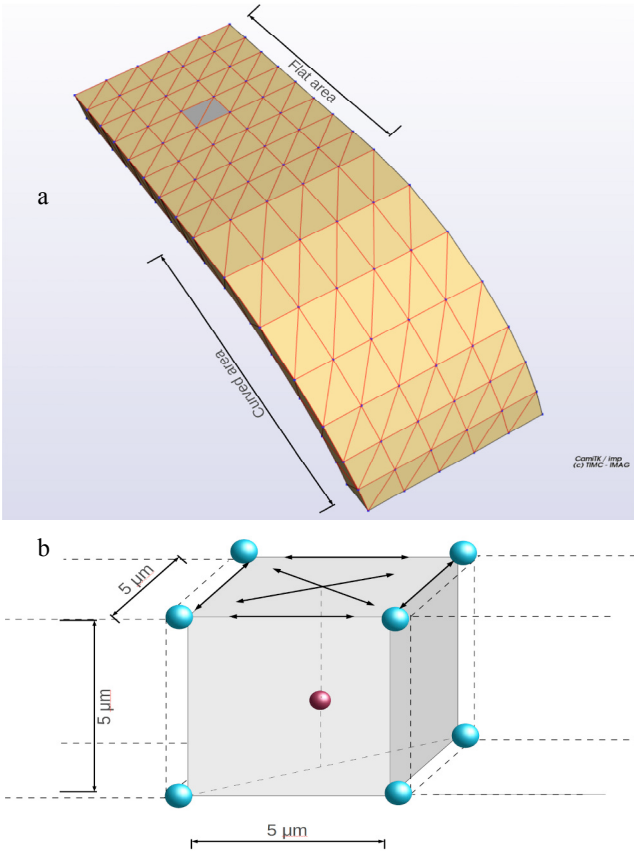

Figure 6: a) Representation of the simulated embryo structure at its initial shape and b) of an individual cell located at area of the centre row of the structure with its centrosome in red.

In our approach, the structure consists of 75 cells arranged in 15 columns of 5 cells each. The first 8 columns form the central part of the structure. The curvature of the structure starts at column 9 and ends at column 15, for a total curvature of  $90^\circ$  (Figure 6a). Each cell is modelled as a hexahedral object, composed of 9 particles. 8 particles are used as the vertices of the hexahedron and one particle is located in the middle, denoting the centrosome of each cell. The cells, with the aid of a biomechanical library, are defined as individual physical objects, with three distinct characteristics: incompressibility, elasticity and contractility. The structure is represented on Figure 6 at its initial shape and an individual cell is located at the central row of the structure. The grey cell corresponds to the cell presented in Figure 6b. The cells of the central area are modelled by cubes with edges of  $5\mu\text{m}$ , resulting to 6 facets of initial surface equal to  $25\mu\text{m}^2$ . The initial volume is  $125\mu\text{m}^3$ . Muscular forces (black arrows) connect the particles of the top facet of the cell. The red sphere represents the centrosome, initially located at the centre of the cell. The particles are modelled as nodes with the ability to interact with their environment. They are defined by their position and their mass. Elastic and muscular forces are applied on them and they can also be submitted to boundary conditions. Their combined displacement is the crucial factor that affects the cell deformation and movement. The

incompressibility algorithm, uses the facets geometry and a displacement constraint, to keep the volume of cells constant. Elasticity forces are defined between neighbouring particles in order to model the tissue reaction against deformation (Henon et al., 1999; Promayon et al., 2003). The elasticity parameters have a small value, so that the cell shape can be modified quite easily by other forces. As a result, we have deformable cells, with nearly unchangeable volumes (which imitates the behaviour of cells *in vivo*). In addition, using muscular forces, we can induce the contraction of cellular objects similar to those due to the Myosin excess (Patwari and Lee, 2008). Using a higher value of the elasticity parameter for the centre particle (centrosome), we ensured that this particle stays close to the centre of the cell, even when the cell is deformed. This allows us to model the rigidifying effect of the cytoskeleton. *In vivo* experiments have shown that neighbouring cells form Adherens Junctions (AJs), which contain complexes of the transmembrane adhesion molecule E-cadherin and the adaptors  $\alpha$ -catenin and  $\beta$ -catenin (Gumbiner, 2005; Martin et al., 2010). In addition, these AJs are formed in the apical areas of the lateral surfaces of the cells (Tepass and Hartenstein, 1994; Oda and Tsukita, 2000). In our model, we have considered AJs to offer very strong linking between cells. Therefore, the vertices of the hexahedron are merged, summing up the forces and constraints of all concurrently surrounding cells. This allows a faster propagation of the forces during the simulation.

## Simulation

Particles at the top of each cell in the central row are linked by muscular forces, which are used to model the forces applied by the orthogonal perpendicular Myosin fibres (Figure 6b). The norm of these forces for each particle is the same, resulting from a uniform distribution of forces along the structure, as suggested in (Brodland et al., 2010). More, boundary conditions are applied to the movement of some particles to verify the symmetry of the simulation (Figure 7):

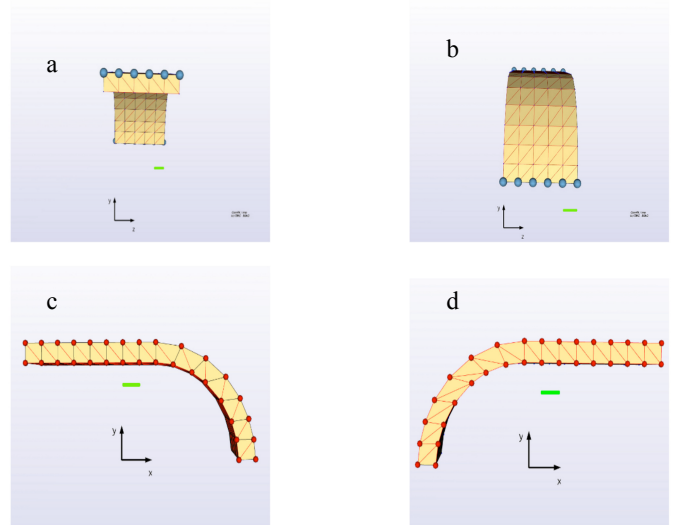

Figure 7: Representation of the boundary conditions imposed on the simulated embryo structure.

Figure 8: Simulation of the ventral furrow invagination process in *Drosophila melanogaster*.

i) the first boundary condition implies that structure edges cannot move in any direction (Figures 7a,b), ii) the second is applied on the side parts of the structure (Figures 7c,d).

The particles can “slide” on the x and y axis but they cannot move on the z axis. These boundary conditions allow the simulation to consider that this model is a part (Figure 8) of a bigger structure, with cells expanding from all sides, in order to form a tubular shape, as presented in Figure 9. At the beginning of the simulation, all the particles are submitted to forces of equal value. This is achieved by applying uniform elasticity and contractility coefficients along the structure. The simulation is divided in time-steps. Each time-step corresponds approximately to 0.05 seconds. At each time-step, the following processing takes place:

- the forces are summed up on all the particles and integrated along the structure using a classical integration scheme,
- the velocity and position of each particle are calculated and integrated also along the structure,
- the constraints are applied (incompressibility and boundary conditions).

In Figure 8, we present the geometry obtained for four different instances of the simulation, from three different angles. In the first row, the geometry is shown from the top, in the second row, it is shown from the bottom and in the third row it is shown from the side of the structure. In next papers to appear, we will provide videos of the entire simulation from all three points of view. At the beginning the cells in the centre row are contracting due to the activation of the Myosin fibres (after entering in the Bottle cells attractor of the previous Section). This contraction pulls all the cells of the model towards the centre. Due to the initial geometry of the structure, as shown in Figure 8, the vertical component of the force applied on the particles of the curved area causes the particles to move downward. As the cells located on the centre

row of the curved part move downward, they concurrently pull the other cells of the structure as well, due to the cell-cell bonds. As a result, all the cells start to move downwards (see Figure 8).

Figure 9: Simulation of invagination starting at the *Drosophila* embryo extremities (Bottom from (Martin et al., 2010)).

An important factor concerning the invagination process is the surface/volume ratio. In vivo experiments have shown that, as the phenomenon proceeds, the area of the cell in contact with the nourishment fluid decreases (Leptin, 1999). On the other hand, cell volume increases. As a result, the surface/volume ratio decreases with time. It has been noted that it can decrease up to a certain threshold, after which the cell tends to divide (Figure 9) as observed in (Cui et al., 2005).

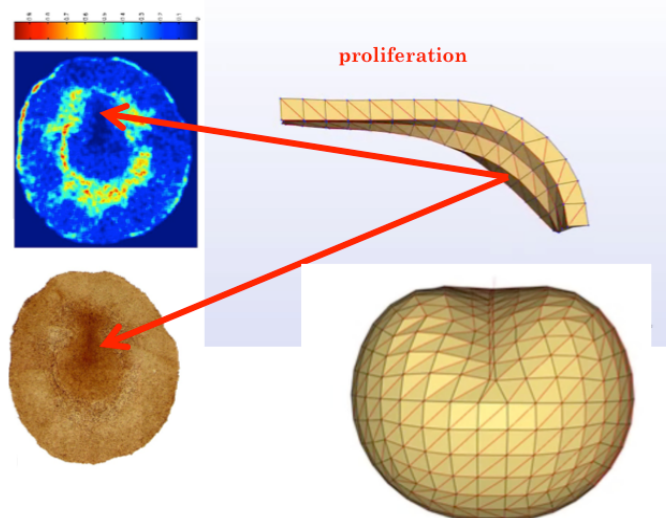

Figure 9: Proliferation occurring at the most invaginated part of the *Drosophila* embryo extremities, the Top left showing a BrDU pre-mitotic S-phase activity from (Cui et al., 2005)).

## Conclusion

We have shown in this paper that the general architecture of a genetic regulatory network involves several genetic circuits, which are crucial for imposing a dynamics having only few attractors, corresponding to few functions to fulfil. This small number of attractors is well controlled by the existence of circuit intersections as well as by the presence of an aspecific inhibitory “noise” from small RNAs, like miRs and mitomiRs.

The Weizmann Institute of Science  
Israel  
dharel@weizmann.ac.il

## Abstract

The talk shows how techniques from computer science and software engineering can be applied beneficially to research in the life sciences. We discuss the idea of comprehensive and realistic modeling of biological systems, where we try to understand and analyze an entire system in detail, utilizing in the modeling effort all that is known about it. I will address the motivation for such modeling and the philosophy underlying the techniques for carrying it out, as well as the crucial question of when such models are to be deemed valid, or complete. The examples will be from among the biological modeling efforts my group has been involved in: T cell development, lymph node behavior, organogenesis of the pancreas, and fate determination in the reproductive system of the *Caenorhabditis elegans* nematode worm. The ultimate long-term “grand challenge” is to produce an interactive, dynamic, computerized model of an entire multi-cellular organism, such as the *C. elegans*, which is complex, but well-defined in terms of anatomy and genetics.

# Do We Need a Theory in the Era of Massive Data Flow?

Takashi Ikegami<sup>1</sup>

<sup>1</sup>Department of General Systems Sciences  
The Graduate School of Arts and Sciences  
University of Tokyo  
ikeg@sacl.c.u-tokyo.ac.jp

## Abstract

Massive Data Flow (MDF) is everywhere these days; from data about neural cells, social insects and genetic networks, to Lifelog (digital storage of a person's visual and audio life log) and SNS (Social network service) data streams. Current web and device technology has made it possible for us to record detailed and massive data flows of artificial and real living systems.

But how can we analyze and understand MDF? Can a simple toy model based on a plausible narrative and simulation still tell us something? Concepts like “the edge of chaos” and “self-organized criticality” once helped us to understand living systems, but we do not know whether the same concepts can be useful to MDF.

I think studies of artificial life in MDF need larger models, because we need the strength of models that overcomes MDF. Possible larger models do not have to mimic existing living creatures but can be larger, in the sense of novel invention and utilization of space and time. In other words, to understand the complexity of MDF is to recast and reconfigure it into a larger artificial model. Indeed, I myself made a large model called “MTM” (Mind Time Machine) in 2010 that ran for three months in an open space, receiving massive visual data from the environment with 15 cameras, processed by internal neural dynamics with a learning capability, and showing sustainable complex adaptive dynamics.

We need a theory to make large artificial life models and to take them out into the real world.

# Answering Descartes: Beyond Turing

## Foreword

Article reproduced with permission from a chapter in S. Barry Cooper and Andrew Hodges (editors): *The Once and Future Turing: Computing the World*, Cambridge University Press, to appear 2012.

## Introduction

The first half of the 20th Century was filled with a stunning group of scientists, Einstein, Bohr, von Neumann and others. Alan Turing ranks near the top of this group. I am honored to write in this Centennial Volume commemorating his work. How much do we owe one mind? His was a pivotal role in cracking the Nazi war code that profoundly aided the defeat of Nazism. His invention of the Turing machine has revolutionized modern society, from universal Turing machines to all digital computers and the IT revolution. His model of morphogenesis, the first example of a “dissipative structure”, to use Prigogine’s phrase for it, is one I have myself used as a developmental biologist.

I rightly praise Turing, but seek in this chapter to go beyond him. The core issue is the human mind. Two lines of thought, one stemming from Turing himself, the other from none other than Bertrand Russell, have led to the dominant view that the human mind arises as some kind of vast network of logic gates, or classical physics “consciousness neurons”, to use F. Crick’s phrase in *The Astonishing Hypothesis* (1), connected in the 10 to the 11th neurons of the human brain.

I think this view could be right, but is more likely to be wrong. My aim in this chapter is to sketch the lines of thought that lead to the standard view in computer science and much of neurobiology, note some of the philosophic claims for and doubts about the claim, but most importantly I wish to explore the emerging behavior of open quantum systems, their new physics, and, centrally, our capacity to construct what I will call non-algorithmic, non-determinate yet non-random Trans-Turing Systems. As we shall see, Trans-Turing systems are not determinate, for they inherit the indeterminism of their open quantum system aspects, yet non-random due to their classical aspects. They are new to us, and may move us decisively beyond the beauty but limitations of Turing’s justly famous, but purely classical physics, machine.

Beyond the above, I shall make one truly radical proposal that I believe grows out of Richard Feynman’s famous “sum over all possible histories” formulation of quantum mechanics,(2). This formulation is fully accepted as an equivalent formulation of quantum mechanics. I will show that Feynman’s formulation evades Aristotle’s Law of the Excluded Middle, while classical physics and, a fortiori, algorithmic discrete state, time, classical physics, Turing machines, obey the Law of the Excluded Middle. Following philosopher C.S. Pierce, who pointed out that “Possibles” evade the Law of the Excluded Middle, while Actuals and Probable obey that Law,(3), and Alfred North Whitehead,(4), I shall propose for our consideration a new dualism, Res potentia and Res extensa, the realms of the ontologically real Possible and ontologically real Actual, linked, hence truly united, by quantum measurement. In contrast, the dualism of Descartes, Res cogitans, thinking stuff, and Res extensa, his mechanistic world philosophy, have never been united. I believe Res potentia may be a consistent and new interpretation of “closed” quantum systems prior to measurement. These ideas and other much less radical ones resting on open quantum systems lead to new and testable hypotheses in molecular, cellular, and neurobiology, and, hopefully, a new line of ideas in the philosophy of mind including proposals about: how mind acts acausally on brain, an ontologically responsible free will, what consciousness IS, the experimentally testable loci of qualia as associated with quantum measurement itself, the irreducibility of both qualia and quantum measurement, the unity of consciousness, i.e. the “qualia binding problem” and its cognate “frame problem” in computer science. From these, technological advances in numbers of directions may flow.

## Mind as Machine

As noted, there are two strands, from Turing and the Turing machine, and from Bertrand Russell, that both lead to the view of the mind as a classical physics “computing machine”.

The strand from Turing is well known. It begins with the Turing machine, the very definition of algorithmic behavior. To recall, a Turing machine consists, in general, of an infinite tape divided into squares. On each square one of a finite number of more than one symbol, say “0” and “1”, is written. A reading head begins poised over one square. The head

contains two sets of rules. The first rule prescribes the following actions: If situated over a tape square with a given symbol written on it, the head will stay where it is, move one step to the left or right, erase the symbol on the square below it, and write a symbol from the defined alphabet of discretely different symbols on that square. The second rule specifies that under the above conditions, the reading head will change from one of a finite number of discrete internal states to some internal state. Thereafter, the system iterates. There is, in addition the crucial “halting state”.

Turing showed that any recursive computation that could be carried out could be carried out by a universal Turing machine. From this followed wonderful theorems about the formal undecidability of the “Halting problem”, the demonstration that most irrational numbers were not computable, and other remarkable advances.

The feature of the Turing machine I wish to emphasize is that it is *absolutely definite* or *determinate*. Given the symbols written on the tape, and rules in the reading head, its behavior at each step is fully determined. This determined behavior is essential to the algorithmic character of the Turing machine. Because it is determinate, the Turing machine is bound by classical physics. However, Turing machines are discrete state and discrete time systems, while classical physics more generally is based on continuous variables and continuous time and is also deterministic, and can, since Poincaré, exhibit deterministic chaos.

Computer scientists often distinguish between algorithms that may halt with an answer, and those that are “processes”, such as Holland’s Genetic Algorithm (5), which just continues or halts at some defined success criterion.

Turing, in the Turing Test, or “Imitation Game” (6), soon turned to the question of whether the human mind was itself a Turing machine. He thought, after careful consideration, that the answer was “Yes”. He did, however, retain doubts, partially reflected in his use of humans, not algorithms, as the judges in the Turing Test. Turing scholars rightly admire his capacity to doubt himself.

## Russell and Onwards to Mind as Machine

At the turn of the 20th Century, Bertrand Russell, having just published with Whitehead the *Principia Mathematica*, turned to the problem of maximally reliable knowledge of the “external world”. We could be wrong, he reasoned, that there was a chair in the room. But we could hardly be wrong that “We seemed to be seeing a chair”. That is, statements about our experiences, say visual, were less corrigible, or error-prone, than our statements about the external world. Russell and his contemporaries, including the young Ludwig Wittgenstein, hoped to build up knowledge of the external world from experience itself.

Pause and look at the room or world around you. You experience a “whole” visual field called in neuroscience, the “Unity of Consciousness”. This unity will be central to my interests. However, Russell threw away the Unity of Consciousness in his very first philosophic move. He invented, whole cloth, “Sense Data”, such as “Red here” or the musical note “A flat now” (7). That is, Russell shattered the unity of consciousness into bits, soon to be related to computational “bits”.

Russell’s next step was to invent “Sense data statements”. “It is true for Kauffman that ‘A flat now’”, (7).

Why did Russell make this move? Because his *Principia* hoped to construct the entire mathematical world from first order predicate calculus. Then the hope was that the statement, “There is a chair in the room”, could be translated into a *logically equivalent statement* comprised of a finite list of true or false sense data statements and quantifiers such as “There Exists”, and “For All”. If the move worked, knowledge of the external world would be set on a firm foundation.

The discussion took perhaps 40 years, but the move, culminating in the *Tractatus Logico-Philosophicus* by Wittgenstein (8), did not work. The statement, “There is a chair in the room” could not be translated into a logically equivalent set of sense data statements in the first order predicate calculus. Philosophers gave up on the idea that there was a “basement” language from which all other knowledge of the world, captured in propositions, could be formulated.

Famously, the later Wittgenstein, in his transforming opus *Philosophic Investigations* (9), pointed out that there was no basement language. Rather, language about legal proceedings could not be translated into logically equivalent sets of statements about ordinary human actions. Each “level” constituted a “language game”, not reducible to a lower level. Thus: “Kauffman is guilty of murder.” requires for its understanding a co-defined set of concepts such as “trail”, “jury”, “legally admissible evidence”, “legally competent to stand trial”...that cannot be translated or “reduced” into sets of statements about ordinary human actions.

This step is critical, for it says that there is no logical procedure, surely no first order logic, to get from a lower level language game, here normal human action, to a higher level language game, here legal language. But then there is no first order logic “algorithmic procedure” to get from the lower to higher language. Yet we learn legal language. This is one line of argument that the human mind is not merely algorithmic.

Despite some philosophers giving up on a basement language, the early cyberneticians, W. McCulloch and W. Pitts, in 1943 published a seminal paper that would lead to the contemporary theory of neural networks and “connectionism”.

McCulloch and Pitts showed that in a network of on/off formal neurons, constructed in a feed forward network, N formal neurons per row and M rows, and in which the input row “neurons” could be placed in any arbitrary combination of “1” and “0” states, the network, with arbitrary threshold Boolean functions such as *and*, *or*, and *not*, could compute any logical function on the “states” of the input neurons.

Implicitly, they identified the “1” or “0” state of a formal neuron with the truth or falseness of a Russellian sense data statement, such as, “For Kauffman, ‘A flat now’ is true”, which might be encoded by a “1” on the first neuron in the input layer to the feedforward network of formal neurons.

More generally McCulloch and Pitts considered networks with feedback loops.

They entitled their paper, “A logical calculus of the ideas immanent in nervous activity” (10).

In this step, McCulloch and Pitts set the stage for the now generally accepted view in computer science, neurobiology, and much of the philosophy of mind, that an “idea” in the

mind was logically identical to the on or/off states of a set of formal neurons, or in contemporary neurobiology, with the axonal firing or not of members of a set of “consciousness neurons”.

Note that McCulloch and Pitts chose the terms, “immanent in nervous activity”. In some magical way, the sense data features, or sense experiences, or “qualia” are “slipped” into the 1 and 0 behaviors of the formal neural net.

Note further that this conceptual move: 1) assumes that there is a basement language, captured in the “1” and “0” states of the formal neurons. 2) Has, with Russell, thrown away the Unity of Consciousness and will have to reconstruct it. In contemporary neurobiology this issue has returned as the famous “binding problem” ie how does the firing of unconnected “consciousness neurons” become bound into a unity of consciousness, or more simple examples such as this, from F. Crick’s *The Astonishing Hypothesis* (1): Suppose I see a yellow triangle and blue square. Suppose “yellow”, “triangle”, “blue” and “square” are, in fact, processed in different, unconnected, areas of the brain. How do “yellow” and “triangle” become bound together, while “blue” and “square” become bound together?

Following the logic of McCulloch and Pitts, the early hope was brain “grandmother cells” that fired if and only if you saw a combination of features, sense data, that equaled your grandmother. Now reconsider the number of relational features of your visual field. How many grandmother cells would be required, each to encode by firing “if and only if” presented with one of each of the possible combinations of up to, say 30 features at a time, out of say 10,000 features you can discriminate? The answer is  $(10,000 \text{ Choose } (30))$ , i.e.  $(10,000!) / 9,9770! \times (30!)$  a vast number. Crick (ibid), concludes that the idea does not work, it would take more than the 10 to the 11th neurons to encode all the sets of relational features you see.

One current hope is a 40 Hertz oscillation in the brain. The idea is that if “yellow” and “triangle” neurons fire at the same phase of the oscillation they will be bound, and if “blue” and “square” fire at a different phase, they too will be bound. Well, maybe, but how do we squeeze maybe trillions of combinations of relational degrees of freedom into different phases of a 40Hertz oscillation? I find it implausible. While detailed work on binding is beyond the scope of this chapter, in general the issue remains binding anatomically unconnected classical physics neurons and their presumed qualia, or experiences.

Note that this binding problem arises, descendant from Russell, with the idea of sense data and sense data statements, true or false, as a *digital and propositional encoding* of our experience of the world in our Unity of Consciousness. Below I will offer an unexpected *analog and non-propositional* encoding which may solve the binding problem.

But there is another deeper issue: McCulloch and Pitts, and all later neural network theory, cannot meet Wittgenstein’s language game argument that there is no “basement language” and the learning of higher language games cannot be based on algorithmic procedures from that basement language.

Despite the warning of Wittgenstein, connectionism has flowered, much along the ideas above, but with important improvements such as Back Propagation (11), and Hopfield Networks (12), with attractors encoding classes or memories

and content addressable memory. These are now the basis of voice recognitions systems around the world. But the language game problem remains unsolved, so mind seems not to be algorithmic on this ground.

I point to another important line of evidence that the mind is not algorithmic. I ask you to name all the possible uses of screwdrivers: screwing in screws, opening paint cans, tied to the end of a stick to spear fish, rented to locals to spear fish and you take 5% of the catch...Is there a statable list of the possible uses of a screwdriver for all possible purposes? I think not. How would we construct such a list? Know we had completed the list, or at least made it “infinite but recursively enumerable”? Yet we find new uses for screwdrivers and other artifacts all the time. This is the famous “frame” problem of computer science, never solved algorithmically. I believe there *is no bounded or recursively orderable set of functionalities of human artifacts for all possible purposes*, yet we literally discover and invent them all the time in the evolution of the econosphere. We routinely solve the frame problem. If so, the human mind is not always algorithmic.

I note that R. Penrose, in *The Emperor’s New Mind* (13), and *Shadows of the Mind* (14) also argues that the human mind is not always algorithmic based on its capacity to prove incompleteness theorems such as Godel’s theorem and the Halting Problem. I join Penrose, who precedes me, but on different grounds, in thinking the mind is not algorithmic and join him in thinking that quantum mechanics is related to consciousness.

## Mind, Consciousness, and the Mind as Machine

Two major positions can be taken with respect to mind as a classical physics, and further, a discrete space, time, and state algorithmic computational machine with inputs from a discrete space, time and state environment. First, we are not conscious at all, but are zombies. This view is discussed by Daniel Dennett in *Consciousness Explained* (15), which is, in part, a sophisticated form of logical behaviorism making use of an extensively developed computer science framework. A contrary argument is made by John Searle in his debated but famous Chinese Room argument which claims to show that mind is not a Turing machine, which is merely syntactic in its manipulation of symbols having no semantics, hence the Turing machine cannot experience the meanings of words (16).

In one form or another, the view of the mind-brain system as a network of classical physics neurons, with continuous variables, and continuous time, interacting in classical physics causal ways via action potentials, vast networks with classical physics inputs and outputs, is the dominant view today. Gerald Edelman, *Bright Air, Brilliant Fire* (17), Francis Crick, *The Astonishing Hypothesis* (1), John Searle, *The Mystery of Consciousness* (16), and most working neuroscientists hold this view. According to Searle, Functionalists such as H. Putnam and D. Lewis are “property dualists” who see mental terms such as “believe” as constituted by a classical physics causal network, whether made of neurons or beer cans. Searle asserts that functionalists do not mean by mental terms the actual experience of, for example, pain (16). These two

paragraphs cannot characterize the vast scholarly work above, yet these efforts neither answer Descartes, introduced just below, nor finds a home for consciousness itself.

Then whence consciousness, experience, qualia? A popular view is that at some level of complexity of a network of logic gates, whether electronic, water bowls pouring into one another above and below a 0/1 threshold, or classical physics continuous time and state neurons, consciousness will “emerge”. It is popular to point out that a single H<sub>2</sub>O molecule is not wet, but a sufficient collection of them is. So too, consciousness can emerge.

Perhaps consciousness can so emerge, but here is the first deep problem. If the emergent consciousness is a classical physical “process”, for example an electromagnetic field as some argue, then it is a deterministic classical physical system. Consider Newton’s three laws of motion and universal gravitation, and billiard balls moving on the table. The boundary conditions of the table and current positions, momenta and diameters of the balls entirely determine the entire future trajectory, perhaps deterministic chaos, of the sets of balls.

But if the mind-brain is a deterministic machine, we can have no ontologically real and responsible free will. I walk down the street, kill the little lady with a frying pan, but I am not responsible. I was physically determined to whack her. Even in the face of deterministic chaos I have no ontologically real responsible free will, merely perhaps the epistemic illusion of one.

Thus, the familiar view, derived from Turing and Russell, may be right, consciousness may be a classical physical “something”, but we buy it at the price of no ontologically real responsible free will.

It is a huge price to pay. I will offer below a set of ideas that appear to afford us, among other things, an ontologically responsible free will.

There is another huge set of problems, derived from Descartes in 1637 in his Discourse on Method. Descartes postulated a famous dualism (18): *Res cogitans*, thinking stuff, and *Res extensa*, his mechanical world view which led, a century later to Newton and celestial mechanics, and thence to classical physics.

But the problem immediately arose how *Res cogitans* is connected to *Res extensa*. Descartes proposed the pineal gland. The idea does not work.

Given Newton, here is the issue: If the brain is a deterministic dynamical system, like the billiard balls on the table, then the current state of the brain is entirely sufficient for the next state of the brain. Then there is *nothing for mind to do. worse, there is no way for mind - experiences - to act on brain!* What should mind do, some- magical-how cause the billiard balls to swerve despite the sufficiency of Newton’s laws?

This central problem arises due to the *causal closure of classical physics*. It is due to causal closure that we claim Newton’s laws, plus the initial positions and momenta and diameters of the billiard balls and boundary conditions, plus Newton’s laws in differential form, once integrated, are entirely sufficient to yield the entire future trajectory of the balls on the table.

Thus, the Turing model of the Machine Mind leaves us with no free will, and mind, experiences or qualia, if they can

arise at all, as unable to affect the classical physics machine aspect of the mind-brain system. We retreat to mind as a mere epiphenomenon, of no effect in our actions as humans, or a “compatibilism” which rejoices that at least as deterministic systems we can train one another to be moral machines.

In truth, we have been stuck with this cycle of problems since Descartes. Turing machine minds are frozen in the same way.

If the central problem above is due to the causal closure of classical physics, then I believe we must forsake the limitations of classical physics and purely classical physics “consciousness neurons” for a view that embraces the non-determinant behavior arising from quantum mechanics.

I turn now to such a radically different approach to the mind-body problem. It will take us through open quantum systems, the “Poised Realm” between open quantum and classicality for all practical purposes, FAPP, to non-determinate, hence non-algorithmic, yet non-random Trans Turing systems beyond Turing, to my tentative postulate about a new dualism, ontologically real *Res potentia*, the realm of the Possible, and *Res extensa*, the realm of the Actual, linked - hence united - by quantum measurement. This postulate is also an interpretation concerning what the unmeasured Schrodinger wave is “about”, where we have had no idea since the Schrodinger equation in 1927 (19). The postulate of *Res potentia* leads to a resulting idea of consciousness as a participation in *Res potentia*, ie in ontologically real Possibilities and strengthens the independent hypothesis that qualia, i.e. conscious experiences, are associated with quantum measurement. Most of what I shall say is independent of a real *Res potentia*.

But there is more: We escape the digital “propositional” model of mind with the realization that a quantum wave process in a potential well knows in an analog, not propositional or digital, way its potential well boundary condition or “context”, as part of solving the binding problem. I will link this analog “knowing of qualia” to quantum entanglement among many synapses in the brain as candidate loci of quantum behavior, and *quantum measurement* of those entangled degrees of freedom to achieve non-local EPR high correlations (20), hence “binding” of vastly many qualia, one per measurement, to solve the binding problem and achieve the Unity of Consciousness.

## Answering Descartes

With the discovery that chlorophyll wrapped by its chromophore bearing antenna protein can be quantum coherent for 700 femtoseconds or more,(21), “quantum biology” is emerging. I believe, however, that quantum coherence may be only a small part of quantum effects in biology. We biologists may find ourselves learning and collaborating with quantum physicists, and quantum chemists, in untellable ways. This part of the chapter is an attempt to see into this new territory.

## Closed Quantum Systems and the Two Slit Experiment

Many readers will be familiar with the famous two slit experiment (22). A photon gun emits photons, say one per minute, at a screen with two slits close together and behind the screen is a photodetector, say a film emulsion. If either slit is covered, one obtains a bright spot on the photodetector behind the open slit. Stunningly, if both slits are open, one obtains the famous bars of light, dark, light, dark..., the interference pattern. No classical objects, such as classical particles, can yield this result. It is the hallmark mystery of quantum mechanics, QM.

A classical analogy helps understand the subsequent time dependent linear Schrödinger equation of QM. Imagine a sea wall with two gaps, and a beach beyond. Let a series of plane waves approach the wall. As it passes through the gaps, each wave yields two semicircular wave patterns that approach the beach. If these semicircular patterns overlap at the beach, there will be points on the beach where the crests of the two wave patterns coincide, yielding a higher wave crest. Similarly there will be beach points where the troughs of two waves coincide yielding lower troughs. But there will also be points on the beach where the peak of one wave coincides with the trough of another wave and the two will cancel entirely.

The Schrödinger time dependent linear wave equation produces similar waves. Where peaks and peaks coincide, or troughs and troughs coincide, one obtains a bright bar of photons in “constructive interference”. Where peaks meet troughs, they cancel yielding dark bars in “destructive interference” and hence the interference pattern. An “action” variable in the equation keeps track of the phases in time and space of the Schrödinger waves.

Quantum “weirdness” arises due to the linearity of the equation, for sums and differences of solutions are also solutions. This linearity permits the famous Schrödinger Cat puzzle in which a cat in a box, prior to measurement, is *simultaneously* both dead and alive.

It is notable that, since 1927, no one knows what is “waving” in the Schrödinger wave equation. Meanwhile, von Neumann’s axiomatization of quantum mechanics (23), includes this propagating Schrödinger wave and the mysterious quantum measurement process. Here each wave has an amplitude. The *square* of the modulus of an amplitude, called the Born rule (24), yields the *probability* that that amplitude will be measured in von Neumann’s Process 1, or “R” process with its controversial “collapse of the wave function” of many amplitudes to only one, which can become classical as in the spot each photon makes on the screen of the two slit experiment. In general, there is, to the best of my knowledge, no agreed derivation of quantum measurement from within QM.

## Open Quantum Systems

The emergence of the classical world from the propagation of the Schrödinger wave equation is a deep mystery. One of the current best hypotheses requires distinguishing a quantum “system” from its “environment” yielding an “open quantum

system” and its “environment”. The key idea is that phase information within the open quantum “system” can be lost, acausally, to the quantum environment. This process is called “decoherence” (25). Then, within the system, the “action” gradually loses information about where the peaks and valleys of the Schrödinger wave “are”, so constructive and destructive interference cannot happen, nor can interference patterns. This interference hallmark of quantum effects is gradually lost and classicality is approached arbitrarily closely, reaching classicality “for all practical purposes”, FAPP.

Decoherence is well established experimentally. It disrupts quantum coherent qubit behavior in quantum computers.

Critically, decoherence is yielding new physics. First decoherence takes time. A typical time scale is a femtosecond. During that time phase information is being lost from the quantum system. The Schrödinger wave equation is time reversible. But decoherence is a dissipative process, so is not fully describable by the Schrödinger equation. New physics is expected and found.

I give three examples of this new physics. We are all familiar with the radioactive decay half life, due to closed quantum system Poisson distributed decay of the radioactive nucleus, whose integral is the familiar half life of exponential decay. In the confirmed Quantum Anti Zeno Effect, the decay is faster than any exponential (26). New physics.

Of interest to us as biologists, decoherence can alter the rate of chemical reactions (27). Decoherence happens in cells. What are the implications for molecular, cellular, neural, biomedical, drug and other behaviors? We don’t yet know.

An essential feature of decoherence is that the weird superposition states, the cat simultaneously dead and alive, decohere very rapidly, leaving what are called one or more “pure states”, if more than one, this is called a mixed state. Thus the cat is either dead or alive, but not simultaneously both. We don’t know which until quantum measurement (Seth Lloyd pc, Miles Blencowe, pc).

Recoherence, including to a new superposition state, is possible for open quantum systems. i. Several papers by Paz et. al., (28,29) and Briegel (30,31), show that a quantum entangled state can decohere to classicality FAPP and recohere again. ii. Imposition of a classical field can induce recoherence (32). iii. The Shor quantum error correction theorem (33), proves that if in a quantum computer some qubits are partially decoherent, measurement can be done and information injected, correcting the qubits back to full coherence.

In summary, and stunningly, for open quantum systems it is just becoming known that both decoherence to classicality FAPP and its *reverse*, recoherence, perhaps to a new quantum coherent superposition state, can occur.

Then, in principle, quantum degrees of freedom, including biomolecules, can “hover” between open quantum behavior and classicality FAPP. It is right to stress, as above, that this may have very large implications for the actions of molecules in cells, and drug discovery, design, and action. After all, we treat biomolecules as classical. We may be wrong.

## The Poised Realm

Gabor Vattay, a quantum physicist at Eotvos University Budapest, Samuli Niiranen, a Computer Scientist at the

Tampere University of Technology, Finland, and I, have proposed “The Poised Realm” between fully coherent quantum behavior in *open* quantum systems and classicality FAPP. Picture a two dimensional coordinate X, Y system. The Y axis rises from the origin, where there is open quantum coherent behavior, via decoherence, to classicality FAPP up the Y axis, and via recoherence down the Y axis to open quantum coherent behavior. The X axis is new, comprising “order”, “criticality” and “chaos”. The two axes box in the Poised Realm. The X axis, order, criticality, and chaos is well defined in the classical limit and now is being extended to embrace partially open quantum behavior in the presence of different extents of decoherence and recoherence.

Motion out the X axis from the origin, characterized classically by a frictionless pendulum, can be obtained in at least two ways. The first concerns the “Hamiltonian” of the classical system. A pendulum is perfectly ordered. If released from different initial heights, the frictionless pendulum describes roughly circular orbits in a coordinate space of position and velocity. These circular orbits are parallel, hence neither converge nor diverge. Mathematically, this lack of divergence or convergence is described by a 0 valued Lyapunov exponent. As one moves out the X axis, the Hamiltonian of the system changes. In the ordered regime, the Lyapunov exponent remains a constant 0. But when the Hamiltonian is deformed enough, at “criticality” the Lyapunov exponent becomes slightly positive, the onset of divergence of flows in state space constitute chaos. As the Hamiltonian is modified further, the Lyapunov exponent becomes more positive. This kink at “criticality” is a “second order phase transition”, and well established (34).

A second means to move out the X axis consists in using a “kicked quantum rotor”. A quantum rotor is a one dimensional hoop of states around which a quantized electric charge rotates. It can be kicked by a laser, with intensity K. As K increases in intensity, Vattay (pc), has shown that at first there are many amplitudes propagating, then few, then a single amplitude transforms to “classical” diffusive behavior in momentum space (35).

This classicality is reversible if K is decreased or the Hamiltonian is changed.

Thus, classicality, presumably FAPP, can be *reversibly* achieved up the Y axis or out the X axis.

## **The Non-Algorithmic, Non-Determinate, Yet Non-Random Trans -Turing System.**

I recall here the fully algorithmic Turing machine described above. Several points, sketched above, are essential. First, all contemporary computers are based on the Turing Machine. Second, the Turing machine is *completely definite*. It is the perfect instantiation, restricted to discrete space, time, and state, of classical physics and Descartes’ Res extensa machine world view. iii. This definite behavior of a Turing machine is the definition of algorithmic behavior. iv. Critically, a major contemporary view in neuroscience and computer science and much of the philosophy of mind is that the mind-brain system *must be* algorithmic - some huge system of interconnected logic gates or, more broadly, continuous time and state classical physics neurons firing.

I now describe non-algorithmic, non-determinate, but also non-random Trans-Turing systems. None has been constructed. I believe they are constructible. More the mind-brain system may be not only a vast *non*-algorithmic, non-determinate system, in contrast to classical physics in general, but also a non random Trans-Turing System. More broadly, classical physics is state determined. The mind brain system may be partially open quantum and Poised Realm, hence, via decoherence to classicality FAPP, or via quantum measurement, the mind-brain system may not be a state determined system.

The central ideas are simple. A Trans-Turing System, TTS, “lives in” the Poised Realm, and perhaps involves quantum measurement in the Poised Realm. i. There are quantum degrees of freedom propagating in short lived superposition states that decay rapidly due to decoherence. But these short lived superposition states undergo constructive and destructive interference and will be one basis for a *non*-Determinacy in the Trans-Turing system when coupled to decoherence to classicality for all practical purposes, FAPP, or quantum measurement. Thus TTS are not algorithmic, not determinate and not state determined, in contrast to a Turing machine.

Second, either via decoherence or motion out the X axis or both, quantum degrees of freedom become classical FAPP or via quantum measurement, become classical “Simpliciter”. Both decoherence and measurement are acausal and yield the non-determinant behavior of the Trans-Turing System.

Third, there are, in addition, coupled classical degrees of freedom in the TTS.

Fourth, when quantum degrees of freedom, and either superposition states or pure states become classical FAPP, or are measured, that *alters* in different specific ways the effects of the now classical degrees of freedom on one another, thus alters the non-random collective dynamics of the coupled classical degrees of freedom. In turn this altered non-random classical behavior alters non-randomly the behavior of remaining quantum degrees of freedom.

Fifth, in turn this non-random alteration of the behavior of the remaining quantum degrees of freedom alters non-randomly which of the open quantum degrees of freedom decohere or move out the X axis to classicality FAPP. In particular, higher quantum amplitudes tend to decohere with higher probability. So non-randomly altered quantum behavior, including altered constructive and destructive interference, alters non-randomly which amplitudes become higher, thus alters non-randomly which amplitudes decohere to classicality FAPP.

Sixth, in turn, classical FAPP degrees of freedom can recohere, for example, driven by a coherent electromagnetic field whose intensity and period distribution can be tuned non-randomly thereby injecting information. The recoherent degrees may achieve a new controlled superposition state, thereby altering non-randomly the constructive, destructive, and pure states behaviors among themselves and other quantum amplitudes, thereby non-randomly affecting which amplitudes achieve higher amplitudes and tend to decohere, and also non-randomly altering the behaviors of the coupled classical degrees of freedom in the TTS.

These six are the building blocks of a Trans-Turing System.

A part of a TTS has been realized in a computation by D. Salahub, a quantum chemist at U Calgary and colleagues, in JACS. Salahub et. al.,(36), considered a quantum system of many nuclei and many electrons. The system consists of two potential wells, say A and B. The vertical Y axis is energy. The X axis is a chemical reaction coordinate. The two potential wells overlap at some point in the X and Y plane, in what they call the “seam region”. Here at this seam the nuclei are in a superposition of states, simultaneously A and Not A, B and Not B. Via gradual decoherence the nuclei fall into one of the minima, either well A or well B, and become classical FAPP. But in turn this alters the effect of the now classical FAPP nuclei on the electron cloud which does not rapidly decohere. Thus, if the nuclei are now in well A the electrons behave differently than if the now classical nuclei FAPP are in well B and the electrons behave differently if the nuclei are still a superposition in the seam region.

This model is the first instantiation in quantum chemistry that I know in which some quantum degrees of freedom, here the nuclei in a superposition of A and Not A and simultaneously B and Not B, decohere to classicality FAPP, to well A or well B, and thereby alter the behavior of the remaining quantum degrees of freedom, the non-decohering electrons.

A more refined calculation would allow the many nuclei in this system to decohere in some sequential order. As they do, the newly classical FAPP nuclei will yield a sequential alteration in the behavior of at least the electrons and probably the remaining open quantum system superposition nuclei, as well as the other now classical FAPP nuclei. That research lies in the future as does study of such a system if the classical FAPP nuclei can be made to recohere to some perhaps new superposition state, perhaps by an external field, perhaps by interactions of many such subsystems within a molecule.

The essential points about Trans Turing Systems are:

- i. Their behavior is not Turing definite, both because of constructive and destructive interference of superposition states, followed by falling to a classical FAPP state where high amplitudes preferentially decohere, and remaining quantum pure states will also decohere probabilistically or by quantum measurement. Further, the total constructive and destructive interference behavior, and further controlled recoherence behavior, alter non-randomly which amplitudes achieve high amplitude so decohere preferentially to classicality FAPP with what probabilities, or are quantum measured, by the Born rule, with what probabilities. The ongoing behavior is not definite, hence NOT algorithmic. The behavior is not state determined. The behavior is also non-random.
- ii. The above behavior is, as noted, not “quantum random”, as in the case of radioactive decay, for a further reason: The classical degrees of freedom have their own Hamiltonian, hence non-random dynamics, which may, in addition, affect non-randomly the behaviors of the quantum degrees of freedom, hence which quantum amplitudes, via constructive and destructive interference, become high amplitudes and preferentially decohere and

when or are preferentially measured via the Born rule. The behavior is both non-deterministic, and non-random.

The TTS may receive quantum, open quantum, Poised Realm, and classical inputs and output open quantum, Poised Realm, and classical output behaviors. So it is a non-algorithmic, non-deterministic via decoherence to classicality FAPP or quantum measurement, yet non-random, information processing system. Consequently if TTS, as single or coupled systems are constructible, perhaps in liposomes, or nano-devices, we have a new non-algorithmic, not state determined, and not random “device”, unlike a Turing machine or logic gate, or deterministic classical physical system to consider for the mind-brain system. We no longer are almost forced to the conclusion that mind-brain *must be* classical physics, definite, and either discrete time and state logic gates or continuous time continuous variable deterministic “consciousness neurons, coupled into a huge network. TTS may also take us far beyond the Turing machine technologically.

## A Responsible Free Will

As noted above, the view that consciousness emerges from a vast network of classic physics logic gates or classical physics neurons may be entirely correct. However, it has a big price: We are deterministic so have no ontologically real responsible free will. Such a system could exhibit chaotic behavior, yielding the “illusion” of free will, but such a free will would not be ontologically real, for the classical physics neural system remains deterministic.

But there is another horn to this free will dilemma if we seek an ontologically real and responsible free will and then try to use standard quantum randomness. I have a radioactive nucleus in my brain, I walk down the street, the nucleus randomly decays, and I kill the little old man so my “free will” is ontologically real due to quantum indeterminism. But killing the old man is not my fault, just random quantum chance! I have no *responsible* free will if we use quantum randomness.

But a Trans-Turing system is both *not* deterministic, hence not algorithmic, and *not* quantum random, it is something entirely new. I hope this can break the horns of the standard responsible free will dilemma and allows for an ontologically real and responsible free will. I believe more is needed, building upon the idea of Ross Ashby’s famous homeostat (37), with its subset of “essential (classical physics) variables” that must be kept in bounds, to provide an internal “goal state” for the total system, to begin to yield a non-random but non-deterministic responsible free will.

This starting sketch, even if right, is inadequate. There is no mention of some analogue or actuality of sensory inputs, motor outputs or the capacity of a coupled Trans-Turing System, or set of entangled TTS systems, joined to the classical aspects of the brain, presumably classical physics neural networks, to classify its environments and act appropriately given goals and subgoals. Below, in proposing the testable hypothesis that qualia are associated with quantum measurement, it seems that “experiences” have as a natural dual, that which experiences, the rudiments of an

"I."Agency", on this view, is an elaboration of these rudiments in the total mind-brain system.

I note that R. Penrose (13,14), seeks a non-deterministic, non-algorithmic, yet non-random behavior of consciousness via a modified non-deterministic, so non-algorithmic, yet non-random quantum measurement process, "objective reduction", which might be associated with quantum gravity. Unlike Penrose, who may surely be right, I seek the same non-deterministic, so non-algorithmic, yet non-random behavior in Trans-Turing systems operating in the Poised Realm.

## Answering Descartes: How Can Mind Act On Brain

Due to the causal closure of classical physics, we have remained frozen with the Cartesian problem for 350 years. Mind has nothing to do and no way to do it. I believe that open quantum systems and the mind-brain system as one or trillions of interlocked Trans-Turing systems may afford an answer to Cartesian dualism, for it breaks the causal closure of classical physics. Decoherence is an *acausal process*. Thus if the mind brain system lies in the poised realm, decoherence of "mind" to classicality FAPP allows "mind" to have *acausal consequences for brain*, without acting causally on brain. We have indeed escaped the causal closure of classical physics.

But we want mind to do this many times in our lives. Trans-Turing systems, living in the Poised Realm, where recoherence, perhaps to new superposition states, allows mind to repeatedly decohere to have acausal consequences for material brain.

Quantum measurement can occur in Trans-Turing systems. But quantum measurement, von Neumann's Process 1 or "R" process, is also acausal, and also allows mind to have acausal consequences for brain. More, even should von Neumann's Process 1 or "R" depend upon the Born rule and his square of the amplitudes to achieve the probability of its acausal measurement, the ongoing behavior of the Trans-Turing systems modifies *non-randomly* which amplitudes are propagating and which achieve high amplitudes and tend to decohere or be measured, so the total behavior is non-random. Once measured a classical degree of freedom can flower again into quantum behavior again, allowing repeated acausal mind-brain action. The non-random but non-determinant total behavior may support a responsible free will.

## Res Potentia and Res Extensia Linked by Quantum Measurement

I now come to the most radical proposition in this chapter. It can be false and the remainder of this chapter stay largely intact. I am, with proper hesitation, about to propose a new dualism, Res potentia, the realm of the ontologically real Possible, and Res extensa, the realm of the ontologically real Actual, linked - hence united - by quantum measurement. The very basis of this is quantum mechanics itself.

I turn first to the late 19th Century American philosopher C.S. Pierce (3). He noted that Actuals and Probables obey Aristotle's Law of the Excluded Middle. Here it is: The table is or is not in the room. There is nothing "in the middle".

Hence the statement, "The table simultaneously is and is NOT in the room" is a contradiction, always false. Now consider: "The probability of 5234 heads out of 10,000 fair coin flips is simultaneously 0.245 and is not 0.245". It too is a contradiction, always false. Classical physics obeys Aristotle's Law of the Excluded Middle. But, said Pierce, "Possibles" evade the law of the Excluded Middle. "A is possibly true and A is possibly not true." is NOT a contradiction.

Now consider Richard Feynman's (2), "sum over all possible histories" formulation of quantum mechanics, agreed by all to be an equivalent formulation."A photon on its way through the two slits, simultaneously takes all possible pathways through the two slits to the photoreceptor." It follows that the single photon "simultaneously possibly *does* and possibility *does not* pass through the left slit". This is *not* a contradiction.

The critical implication is that Feynman's formulation of quantum mechanics *evades* Aristotle's Law of the Excluded Middle. Therefore, I claim, Feynman's formulation of quantum mechanics is fully interpretable in terms of ontological *real* Possibles, Res potentia. The unmeasured Schrodinger wave concerns Res potentia. Res potentia proposes an answer to what the unmeasured Schrodinger wave is "about".

This is a huge step, not to be taken lightly. I note that Aristotle himself toyed with the reality of "potentia". And British philosopher Alfred North Whitehead in Process and Reality, 1929,(4), proposed ontologically real Possibles which gave rise to ontologically real Actuals which gave rise to ontologically real Possibles.  $P \rightarrow A \rightarrow P \rightarrow A$ .

The idea may be radical, and may be right, but I am not the first to propose it. We will find evidence consistent with the reality of Res potentia below in the Conway Kochen Strong Free Will Theorem. Further, outstanding quantum physicists are very close to the concept of Res potentia. I quote Dieter Zeh:

"in classical physics you can and do assume that only one of the possibilities is real (that is why you call them possibilities). It is your knowledge that was incomplete before the observation. Mere possibilities cannot interfere with one another to give effects in reality. In particular, if you would use the dynamical laws to trace back in time the improved information about the real state, you would also get improved knowledge about the past. This is different in quantum theory (for pure states): In order to obtain the correct state in the past (that may have been recorded in a previous measurement), you need all apparent "possibilities" (all components of the wave function - including the non-observed ones). So they must have equally been real." (38).

Clearly Zeh is saying, "possibilities"... "must have been equally real." Res potentia removes the quotes from "possibilities" to propose an ontologically real Res potentia.

More, a founder of quantum mechanics, W. Heisenberg, often spoke of "Potentia" sometimes as "Probabilities" (39), sometimes as "Possibilities" (40), as a separate ontologically real realm along with ontologically real Actuals. I am following Heisenberg with my Res potentia as a realm of ontologically real Possibles.

See M. Epperson (41), for a cogent discussion of many quantum authors and an ontological dualism based on real

Actuals and real “Probables” which DO obey the Law of the Excluded Middle. I stress again that unlike Descartes Res cogitans and Res extensa, never united, Res potentia and Res extensa truly *are* united by quantum measurement

## What is Consciousness

Philosopher of mind Jerry Fodor quipped that “Not only have we no idea what consciousness “is”, we have no idea what it would be like to have an idea what consciousness “is” (42).

To my surprise, Res potentia leads to an obvious idea about what consciousness IS. Consciousness is a participation in The Possible, an ontologically real Res potentia.

I offer three pieces of evidence:

1. Where is the possibility I will skate across town reading the NY times and not be hit by a car? I think we all feel that the “possibility” itself is not spatially locatable, it is not spatially extended.
2. Now consider your experienced visual field. Where is your experienced field located? I think we all sense that our experienced field is not located spatially. It is not spatially extended.
3. Just below I will propose that qualia are associated with quantum measurement and further below hypothesize that entanglement of many quantum degrees of freedom, perhaps among neurotransmitter receptor molecules in anatomically unconnected synapses in the brain, may, by each being quantum measured, yield causally non-local Einstein, Podolsky, Rosen, EPR, high correlations of now bound qualia (20), to solve the “qualia binding problem” in neurobiology. Non-local correlations are “non local” because they are beyond speed of light signaling and “instantaneous”, hence also “non-spatial”.

This non-spatial character of “Possibilities”, Experience and Non-Local EPR quantum measurements may be happenstance or a clue. Taking this parallel as a clue may lead us forward in new ways.

## Qualia may be Associated With Quantum Measurement

Where is it natural to locate experience itself, the blueness of blue, the taste of wine, qualia? I suggest qualia are associated with quantum measurement, ie Possible “becomes” Actual, Possible  $\rightarrow$  Actual. As we shall see, this leads to testable consequences. It is not a bald hypothesis standing alone, for as just noted I will propose below that quantum entanglement among many quantum degrees of freedom in anatomically unconnected synapses, and non-local EPR correlations achieved by a set of quantum measurements of these entangled degrees of freedom may help solve the “qualia binding problem” and the Unity of Consciousness issue. Thus solving the binding problem may require the hypothesis that quantum measurement is associated with qualia. The hypothesis should be testable in the brain. More, entanglement to solve the binding problem is testable. I note that physicist

H. Stapp has different but somewhat related ideas (43) See also Penrose (14).

A critical feature of quantum measurement, my physicist friends assure me, is that it has never been derived from within quantum mechanics. Granted Res potentia, such a derivation may be disallowed. “X is Possible” does *not* imply “X is Actual”. Our difficulties with such a derivation since 1927 may be ontological, not technical - mathematical. If Res potentia is ontologically real, the same ontological issue may bear on our failure to unite General Relativity and Quantum Mechanics: the “X is Possible” of unmeasured quantum mechanics does *not* imply the “X is Actual” of General Relativity.

On Res potentia, a second feature of measurement becomes equally important. What is the “becomes” of Possible “becomes” Actual? What is the status of “ $\rightarrow$ ” in  $P \rightarrow A$ ? It is not a classical becoming like water freezing, nor the unitary propagation of the Schrodinger wave. As a “becoming” it seem not to be an *existing state* at all. Qualia are a “becoming” not an “existence”. Nor can “ $\rightarrow$ ” be a mathematizable deductive entailing process, for if it were, it would enable deduction from “X is Possible” to “X is Actual”, which is invalid if Res potentia is real. Then there is no mechanism for the quantum measurement captured in von Neumann’s “ad hoc” Process 1 or “R” projection process.

The above paragraph depends upon the reality of Res potentia. But the proposal of a real Res potentia ties to the recent, 2009, Conway Kochen Strong Free Will Theorem (44), which states that if physicists have free will so do electrons, that the world is non-determinant, that there can be no mechanism for quantum measurement, and that the relevant property does not exist before measurement. This theorem rests on free will for the physicist. But above I have argued that Trans-Turing systems in the Poised Realm, *without relying on an ontologically real res potentia*, may afford an ontologically responsible free will. Responsible free will may well require qualia, experience, which I propose is associated with quantum measurement. This again is a proposal that does not require the reality of Res potentia. But a responsible free will supports the claims of the Strong Free Will Theorem. Conversely, this theorem states that, given the free willed physicist, the world is non-determinant. This is consistent with the hypothesis of the reality of *res potentia*. More, by this theorem, if qualia are associated with quantum measurement, there is no mechanism for that measurement. But measurements yield classical degrees of freedom that, as such, can have classical causal effects on the classical world. Mind, qualia, can, via acausal measurement, act causally on the world classically. Perhaps, as I propose below, neurotransmitter receptors are the loci of quantum measurement and qualia. Then the classical variable consequences could alter post synaptic voltage gate behaviors leading to neural firing or not. In turn qualia themselves emerge as irreducible.

The vice of this view is that it hides the mystery of qualia in the mystery of measurement. The virtue of this “hiding” is that it may explain, at last, why we cannot isolate or pin down an irreducible character of qualia. Philosopher David Chalmers (45), also proposes on independent grounds that qualia are irreducible.

I stress that this hypothesis does not say what qualia *are*.

This hypothesis is testable. Anesthetics bind to hydrophobic pockets in neurotransmitter receptors in synapses (46). If they freeze receptors so they cannot quantum measure, no more qualia can arise. Moreover, *Drosophila* can be anesthetized by ether. Select for ease of being anesthetized and seek the molecular components involved in easy anesthetization. The normal, or wild type, versions of these molecules may be involved in consciousness and their quantum and quantum measurement properties studied.

If I assume qualia are associated only with measurement, a potential role for unmeasured quantum behavior in the mind-brain system could be unconscious mental processing, which may have classical consequences via decoherence to classicality FAPP, without measurement. Possibly this bears on Libet's results of neural activities 200 or more milliseconds before conscious awareness of a decision to act (47). This too should be testable.

If qualia ARE associated with quantum measurement, it seems natural that the dual of "experience" is that which experiences, a rudimentary "I". From this rudimentary "I" in the entire mind-brain system with its inputs and outputs, my hope is that full "Agency" and an ontologically real and responsible free will can be found.

## Standing the Brain on its Head

I begin with a stunning fact. The Box jelly fish, with only a loose neural net, no evolved brain, but eyes that have evolved to see shape and color, swims at five knots adroitly avoiding obstacles (48). An evolved brain is not needed for these feats. Also choanoflagellates, single cell precursors to the animals, have many molecular components of synapses (49).

Many readers of the chapter know the neuroanatomy of the human brain and much of its physiology. In brief, we have about 10 to the 11th neurons, each with an average of 6000 synapses. Cell bodies have descending axons which may or may not branch, but each ends on synapses associated by synaptic spikes on dendrites in arborizations which lead into cell bodies. When an action depolarization potential travels down an axon to a synapse, presynaptic vesicles release one of a set of neurotransmitters, such as GABA, which crosses the synaptic cleft to the adjacent dendrite of the post synaptic neuron, and binds to post synaptic neurotransmitter receptors which are often in clusters of many proteins. In turn, often this leads to opening of an ion channel, a transient flow of ions, and a very short term depolarization or hyper-polarization (excitatory or inhibitory respectively) of the tiny local patch of dendritic transmembrane potential. These local changes flow to the cell body and are summed. If the resulting transmembrane potential at the cell body is more than - 20 mV, an action potential is initiated and travels down the axon. Most neurobiologists think classical physics action potentials in neurons carry a "neuronal code" underlying consciousness.

In Francis Crick's Astonishing Hypothesis (1), he notes in a throw away line, that vast amounts of information about tiny time-space alterations in dendritic transmembrane potentials and behaviors of synaptic molecules are thrown away in neural classical physics action potentials.

What if we consider "standing the brain on its head", and supposing that this vast amount of information in and around synapses and local dendritic regions are the "business end" of

the brain- sensory-motor system. This does not vitiate at all the huge amount of work on neural circuitry and classical action potentials and information processing by classical neural action in the brain.

However, it does raise the possibility that the "neural correlates of consciousness" may lie in synaptic and local dendritic, possibly poised realm behavior, possibly in quantum measurement processes.

I note that Beck and Eccles have considered quantum processes in synapses (50)

## Quantum Entanglement, Niiran's idea, and the Binding Problem

Consider, says Crick, a yellow triangle and blue square. Let "yellow", "triangle", "blue", and "square" be processed in different, anatomically unconnected brain areas. How are they bound into yellow triangle and blue square. This is the binding problem. Crick focuses hope on squeezing perhaps millions of distinct sets of features to be bound into different phases of the 40 Hertz oscillation, as I have described.

The first idea I propose is to use quantum entanglement to link quantum processes in different, anatomically unconnected synapses to start to solve the binding problem. Entanglement occurs if a quantum degree of freedom, say a photon, decays into two lower energy photons that go off in opposite directions, even so far apart that even light cannot travel between them in the *interval between quantum measurements of the two entangled photons*. QM says, and it is confirmed over and over, that the *two quantum measurements* will be highly correlated, even though no light or information can have traveled between the two sites. This is "EPR non-local correlation" (20). I stress that in the entangled state, the two photons remain in a *single* quantum state.

I want to try to use quantum entanglement among many synaptic degrees of freedom to try to solve the Binding Problem. Hence, as I have emphasized, it is very attractive to me that these quantum correlations require quantum *measurement* of the entangled degrees of freedom, and I have already supposed that quantum measurement itself is associated with qualia. Then these many entangled degrees of freedom in a *single* quantum state when measured yield qualia that *are* bound. The hypothesis that qualia are associated with quantum measurement does not stand alone, it may afford a part of an answer to the Unity of Consciousness.

Clearly, such entanglement may require long range entanglement among anatomically unconnected synapses and neurons in the brain connecting the "right" set of, say, synaptic molecules. How and whether this may be accomplished is, at present, uncertain, but see below.

Samuli Niiranen had a lovely idea. "If you measure the position and momentum a single classical gas particle in a box, do you know about the shape of the box?" No you do not. "But", he continued, "a quantum wave process in a potential well that serves as its boundary condition "knows" about the shape of that potential well, for example in its measured energy spectrum!". He is right.

Think of music in a room and trying to describe air pressure waves using bits. Now think of 1000 differently shaped drum heads well placed in the room. Their patterns of

vibrations, ie the eigenfunction spectra of the drums bound to drumheads, “know” the music in the room, and do so in an analog embodied way, not a digital or propositional way. A telephone is not digital either.

This leads to the idea that the brain’s sensory system and the whole brain, may tune the synaptic or local dendritic transmembrane potentials in tiny time-space regions of the brain, such as synapses and adjacent local dendritic membranes so they jointly “cover”, like many tuned antennas, the visual scene such that quantum processes in those potential wells, when entangled and measured yield both a Unity of Consciousness and solve the Binding Problem in an analog not digital way.

Two final points. It now appears that increasing the number of entangled degrees of freedom *increases* the quantum EPR correlations. This increase is the opposite of the curse of dimensionality. This helps the binding problem. Second, local actions can alter which quantum degrees of freedom are entangled, perhaps offering an account for serially shifting focus of attention, and might entangle the “correct” set of quantum degrees of freedom for each focus of attention (51).

Can all this be correct? I certainly do not know. But the ideas seem coherent, testable, and jointly seem to offer new purchase on manifold problems.

### “Programming Trans-Turing Systems”

We have known about Turing Machines since the mid 1930s and programming the von Neumann architecture for over fifty years. We have no experience with Trans-Turing Systems, TTS. But we face a problem: How would we achieve a TTS that “does something we want”?

There seem to be two approaches. Simulate the TTS on a digital computer and evolve a population of TTS, or a population of interacting entangled, measured, TTS, to yield the behavior desired. This is analogous to the Genetic Algorithm of Holland (5).

Another approach which may be worth considering is creating self reproducing molecular systems, perhaps autocatalytic sets of polymers in dividing liposomes, supplied with energy by pyrophosphate or in other ways, and capable of open ended evolution. Recent work shows that: 1) collectively autocatalytic sets arise as the diversity of polymers in a reaction set is increased (52,53). 2) Such systems can undergo open ended evolution (54). 3) Liposomes can grow and divide (55). 4) A collectively autocatalytic set in a reproducing container can yield synchronization of the reproduction of each (56). Experimental collectively autocatalytic sets have been constructed (57). Libraries of stochastic DNA, RNA, peptides, polypeptides and proteins can be made (58), so we can test for the emergence of collectively autocatalytic sets.

It is an exciting prospect that work on the origin of life and work on Trans-Turing Systems may come together. More Darwinian preadaptations among such co-evolving protocells generate new, unprestatable biological functions that maintain one or more such protocells, hence solve the frame problem (59). Co-evolving TTS in protocells may well solve the frame problem too.

Work with minimal cells as vehicles for TTS evolution and co-evolution may be possible (60).

In addition, nanotechnology, perhaps with populations of nano-devices that can be subjected to Holland’s Genetic algorithm (5), may prove useful.

## Conclusions

I have argued that classical physics Turing machines as models of the mind are possible, but leave us at best with no free will, and an epiphenomenal consciousness. I believe that we can begin to go beyond Turing, to create non-algorithmic, non-determinate, and non- randomly behaving Trans-Turing systems, living in the Poised Realm, perhaps in self reproducing protocells, perhaps as nano-devices, both open to evolution or co-evolution to achieve useful ends. I propose tentative answers to Descartes about mind and body. Many of the ideas in the Chapter are new science or even radical. They may portend transformations in quantum physics, quantum chemistry, a new Poised Realm behavior of biomolecules hovering between quantum and classical behaviors, a new approach to neurobiology, the philosophy of mind, and the radical possibility of Res potentia with consciousness a participation in The Possible, qualia as irreducible and associated with quantum measurement which also may be irreducible, and entanglement and quantum measurement to achieve a unity of consciousness. I hope these concepts point the way forward for us all.

james.murray@maths.ox.ac.uk

## Abstract

The prognosis for patients with high grade brain tumours (gliomas) is grim and the various treatment protocols such as surgery, radiation and chemotherapy cannot effect a cure. I describe, without any technical details, a simple but very practical model which uses patient data and brain scans to quantify the spatio-temporal growth of such brain tumours. Analysis of the model shows how difficult it is to decide on the tumour volume to be treated and shows why such treatments have so little success. The model simulations can estimate life expectancy for individual patients and show how it is possible to use the patient's past record to predict the efficacy of possible treatments. Recent patient data indicates that calculating such an index of treatment efficacy is indeed a realistic aim. With the increasing discussion about cell phone use and a possible increase in brain tumours, I describe how to obtain an estimate for when a brain tumour started given its size at detection.

## Introduction

High grade brain tumours, glioblastoma multiforme (GBM), are the most aggressive brain tumours and make up more than 50% of all brain tumours. There is 100% mortality rate for patients with such tumours with an approximate median life expectancy of 9-12 months. The various treatment protocols such as surgery (resection), radiation and chemotherapy cannot effect a cure but can sometimes extend survival time. Treatment efficacy depends on various factors such as where the tumour is located in the brain and the size of the key parameters, namely the growth rate and the diffusion rate. Diffusion in white matter is larger than in grey matter. It is the aggressive infiltration of cancer cells which make treatment protocols so difficult to localize. In spite of increasing accuracy of imaging techniques they still cannot detect cancer cell densities sufficiently accurately. The inadequacy of medical imaging is substantiated by the fact that irrespective of the extent of surgical resection or focused irradiation of the tumour it is always followed by multifocal tumour recurrence at or near the edge of the resected volume (Silbergeld *et al.* 1991).

A basic practical model which encompasses the two key elements in the growth of such tumours, namely the invasive

diffusive properties of the cancer cells and their growth rate is qualitatively given by the equation:

$$\begin{aligned} \text{Rate of change of tumour cell density} \\ = \text{diffusion (invasion) of tumour cells} \\ + \text{net proliferation of tumour cells} \end{aligned} \quad (1)$$

The mathematical form which quantifies the various terms in (1) is

$$\frac{\partial c}{\partial t} = \nabla \cdot D(x) \nabla c + \rho c \quad (2)$$

where the various terms in this equation are defined as:

- $c(x,t)$  = glioma cell density, cells/mm<sup>3</sup>, which is a function of the position,  $x$ , in the brain at time.
- $t$  = time, measured in months.
- $D(x)$  = diffusion (invasion), mm<sup>2</sup>/month, which quantifies the invasiveness of the cancer cells at position  $x$  in the brain.
- $\rho$  = proliferation rate (/month) of the cancer cells which gives the turnover time as  $\log 2/\rho$  (months).

The solutions of (2) are unbounded as time increases because of the form of the growth term which implies exponential growth. A more accurate model has in place of  $\rho c$  the expression  $\rho c(1-c/k)$  where  $k$  is a constant associated with the maximum concentration possible in the brain tissue. This equation, with a constant diffusion coefficient, is a classical population equation known as the Fisher-Kolmogoroff equation (Murray 2002). Solutions of it are bounded and exhibit traveling waves. However, in the time scales relevant to glioma growth and patient survival time it does not contribute significantly to the solutions relevant to cancer patients.

With two individual patient brain scans, such as CT, MRI and others, the key model parameters, namely diffusion and cell growth can be calculated. With these we can then predict the subsequent growth of such brain tumours. As illustrated below, analysis of the model shows how difficult it is to decide on the tumour volume to be treated and shows why such treatments can have little success. The model simulations can estimate life expectancy for individual patients and how to

predict the efficacy of different treatments. Patient data indicates that calculating such an index of treatment efficacy is a realistic aim. With the increasing debate on the possible increase in brain tumours as a result of cell phone radiation, realistic and scientific clinical trials will require information such as when a tumour started, how fast it grows and where it is in the brain outside of what can be detected with current brain imaging techniques. Here we show how the model provides a means of estimating the time from tumour initiation and life expectancy from tumour detection for individual patients.

The original model was first proposed and analysed in various situations. The brain was considered to be homogeneous matter bounded by the ventricles and skull (Cruywagen *et al.* 1995). Even with such a simple anatomical model the predictions of the analysis were broadly in line with patient observation of both low and high grade brain tumours. The limitations of current imaging techniques were clear. The model was then used to mimic various accepted medical treatments, specifically radiation, surgical resection (Woodward *et al.* 1996) and chemotherapy (Tracqui *et al.* 1995), Swanson *et al.* (2002), Rockne *et al.* (2010). A three dimensional model was proposed and studied by Burgess *et al.* (1997) who were the first to demonstrate that cancer cell diffusion, mainly ignored up to that time, is a major component of glioma growth. They showed that only those tumours with a low diffusion rate could benefit from wide surgical resection although eventually there will be multifocal recurrence. See Murray (2003) for a full discussion and review which encompasses anatomically correct brains.

### Virtual gliomas: enhanced imaging and current limitations

A major advance in the practical application of the model (1) was the availability of the brain web atlas (Collins *et al.* 1998). This allowed the model to be applied to anatomically correct brains (Swanson *et al.* 2002, 2004, Murray 2003). Among other things it made it possible to refine the gross anatomic boundaries and to vary the degree of motility of glioma cells in grey or white matter: these are biologically significant.

With the BrainWeb it was possible to solve equation (2) in a three dimensional anatomically correct brain in which the grey and white matter is clearly delineated.

The procedure is to evaluate the tumour size from brain scans and, crucially, estimate the parameter values for each patient to obtain the average diffusion coefficient and the average growth rate. There is a lower threshold of detection of cancer cells with all imaging techniques, whether CT or MRI, such as T1Gd and T2 imaging, or microscopic studies. To use the predictive potential of the mathematical model (2), serial imaging of the tumour was used to calculate its volume which was then taken as the volume of an equivalent sphere with radius  $r$ , namely  $4\pi r^3/3$ . We then consider the model to be radially symmetric with a constant diffusion coefficient, based on averaging the values from imaging. Equation (2) then becomes

$$\frac{\partial c}{\partial t} = D \left[ \frac{\partial^2 c}{\partial r^2} + \frac{2}{r} \frac{\partial c}{\partial r} \right] + \rho c \quad (3)$$

We consider that at time  $t=0$  there is a concentrated number of cancer cells,  $N$  cells/mm<sup>3</sup>, at  $r=0$  in which case the solution of (3) is given by

$$c(r, t) = \frac{N \exp(\rho t - \frac{r^2}{4Dt})}{8(\pi Dt)^{3/2}} \quad (4)$$

If the smallest level of image detection is denoted by  $c_1$  cells/mm<sup>3</sup>, then the radius,  $r$ , of the tumour for this cell density is, from (4) on solving for  $r$ ,

$$r = 2t\sqrt{D\rho} \sqrt{1 - \frac{1}{\rho t} \log\left(\frac{c_1}{N}(4\pi Dt)^{3/2}\right)} \quad (5)$$

For large time,  $t$ , the solution (5) gives the radius of detectable tumour and the velocity of growth,  $v$ , as approximately

$$r = 2t\sqrt{D\rho} \Rightarrow v = r/t = 2\sqrt{D\rho} \quad (6)$$

That is, the equivalent radial growth is linear in time.

### Approximate *in vivo* patient survival time

If we consider detection is when the spherical equivalent tumour volume is of radius 15mm and that death occurs when the radius is 30mm the approximate survival time from detection, in the absence of any treatments, is given, from (6), by

$$\begin{aligned} \text{Survival time (months)} \\ = t_{\text{survival}} = t_{r=30} - t_{r=15} = \frac{7.5}{\sqrt{D\rho}} \end{aligned} \quad (7)$$

Typical growth rates vary quite widely, approximately from 1-5 /month and diffusion rates from 1-8 mm<sup>2</sup>/month. The medians for 9 patients in the study by Rockne *et al.* (2010) are  $D=0.9$  mm<sup>2</sup>/month and  $\rho=1.16$ /month which gives a median survival time of 7.34 months.

Survival time, however, depends on where the tumour is mainly situated. If it is primarily in the grey area of the thalamus, for example, the diffusion is smaller and so the survival time is longer, as is clear from (7).

The diffusion in grey matter,  $D_g$ , is smaller than that in white matter,  $D_w$ : they can vary by as much as 100-fold. Swanson *et al.* (2002) defined by  $\gamma$  the ratio of the diffusion coefficient in white to that in grey matter, that is  $\gamma = D_w/D_g$ . An average diffusion coefficient for the entire brain can be defined as the diffusion coefficient in white matter times the volume fraction of brain that is white matter plus the diffusion coefficient in grey matter times the volume fraction of brain that is grey matter. The figures from the brain web database give the fraction of grey matter as 0.5723 and of white matter

as 0.4277 (Collins *et al.* 1998). So an average diffusion is given by

$$D_{average} = 0.5723D_g + 0.4277D_w = D_g(0.5723 + 0.4277\gamma) \\ \Rightarrow D_g = D_{average} / (0.5723 + 0.4277\gamma)$$

Swanson *et al.* (2002a) took as a typical average diffusion,  $D_{average} = 3.9 \text{ mm}^2/\text{month}$  so the diffusion in grey matter from the last equation gives  $D_g = 3.9 / (0.5723 + 0.4277\gamma) \text{ mm}^2/\text{month}$ . They evaluated survival time as a function of  $\gamma$  for a frontal tumour where it is mainly white matter and in the thalamic region where it is mainly grey matter.

Simulations of an anatomically correct brain highlights the problems with current imaging techniques. Figure 1 is a computed solution of equation (2) which shows the detectable tumour at death and the spread of the tumour cells beyond what can be detected by the most accurate current CT or MRI imaging techniques. Simulations of the model thus greatly enhance current imaging techniques to whatever level of cancer cell density is required.

**Figure 1** Computed solutions of equation (1) in a three dimensional anatomically accurate brain. These show the horizontal section of the virtual human brain through the site of the original tumour (+ in (a), \* in (b)). The left image in each is the tumour at diagnosis while the right image is the same tumour at time of death. The thick black contour defines the edge of the tumour that can be detected by enhanced CT. The blue contours outside this black line represent cancer cell densities peripheral to the imaging limits. (a) Tumour in grey matter: the time from diagnosis to death is approximately 256 days. (b) Tumour in white matter: the time from diagnosis to death is approximately 158 days. (Figures extracted from Swanson *et al.* 2002a).

The model described here has been used to quantify the effect of different treatment efficacies prior to their use. Incorporating periodic chemotherapy was studied by Tracqui *et al.* (1995) and Swanson *et al.* (2002b). The model used was equation (1) with a further (negative) term on the right hand side which quantifies the periodic reduction in growth as a consequence of the chemotherapy. Incorporating subtotal and total tumour resection in patient survival was considered by Woodward *et al.* (1996). This involves visually excising a given volume of the tumour in the model simulations. The predictions compared well with the data of Kreth *et al.* (1993). The modeling study (Woodward *et al.* 1996) predicted patient survival rates which, considering the basic aspect of their model, compared surprisingly accurately with the extant data at the time and recently published by Ramakrishna *et al.* (2010). Incorporating radiation treatment was also considered in the model and it has been used by Rockne *et al.* (2010) in the clinical study of 9 patients. A full review and how such treatments are incorporated are given by Murray (2003).

### Estimating the time from tumour initiation

An unsolved problem with all cancers is how to determine when a tumour started. In the case of glioma brain tumours detection is when the tumour volume is approximately equal to an equivalent sphere of radius 3cm in diameter but this also depends on the imaging technique used and where the tumour is in the brain. With the increasing discussion and justifiable concern of the possible increase in brain tumours as a consequence of the ever expanding use of cell phones it is inevitable that serious clinical studies will be carried out in the relatively near future. The paper by Tafforeau *et al.* (2004) clearly demonstrates the serious effect cell phone radiation has on plant growth. They showed that a single 2 hour exposure to radiation emitted at 105 GHz from a (GSM) cell phone resulted in considerable growth deformity. The *Journal of the American Medical Association* article by Volkow *et al.* (2011) reports on an increase in brain glucose in the region closest to the antenna. To date no study has definitively stated that brain tumours can arise from prolonged use of cell phones (I personally believe that there will be an increase in tumour incidence.)

Irrespective of the possible cell phone use connection, knowing when a tumour actually started is useful information which could possibly provide clues and pose relevant questions in any major clinical study.

With the increasing use and the quantitative clinical confirmation of many of the predictions of the model discussed here and in numerous publications since it was first introduced, it is reasonable to use it to obtain estimates of brain tumour initiation times. As a first approximation expression (6) gives the radius of the tumour and its velocity as a function of the diffusion coefficient and growth rate but for large times, mainly from when the tumour is first detectable, that is when it has an equivalent spherical volume of at least diameter 3cm. This however is only valid for sufficiently large times and although useful for calculating approximate life expectancy it is insufficiently accurate to back extrapolate to when the tumour started: it significantly underestimates the time.

**Figure 2** (top) This shows the survival time from initiation for a typical range of diffusion coefficients while (bottom) shows the survival time from detection at an equivalent tumour diameter of 3cm to death at a tumour diameter of 6cm.

We can obtain a considerably more accurate estimate using the exact solution (4) for the cell concentration as a function of time. If  $c_1(r, t)$  is the outermost cancer cell density level of detection when the tumour has an equivalent sphere radius of  $r$  then the time it takes for a density of  $N$  cells to grow and diffuse is given by the solution of (5) for given  $r$ ,  $c_1$ ,  $N$ ,  $D$  and  $\rho$ , namely the value of  $t$  such that

$$2t\sqrt{D\rho}\sqrt{1 - \frac{1}{\rho t} \log\left(\frac{c_1}{N}(4\pi Dt)^{3/2}\right)} - r = 0 \quad (9)$$

There is no analytical solution of this equation but it is possible to use MATLAB to obtain the value for  $t$  for given  $r$ ,  $c_1$ ,  $N$ ,  $D$  and  $\rho$ . This gives the time to initiation for all radii  $r$ , not only the radius at the smallest detection but whenever the tumour is first observed. It also gives a more accurate

estimate for the survival time by assigning the radius to be 3cm. We do not know how many cancer cells are required before they start to diffuse nor an accurate value for the detection level  $c_1$ . By way of example we chose  $c_1/N$  in (9) to be 80,000. Figure 2 illustrates the times from initiation for a typical range of growth rates and diffusion coefficients.

From Figure 2 the effect of higher growth rates play a smaller role than diffusion variability while at low growth rates the interplay between growth and diffusion is more complex.

# Prospects for Machine Embryogenesis

Jordan Pollack<sup>1</sup>

<sup>1</sup> DEMO Laboratory  
Brandeis University  
Waltham, MA, USA  
pollack@brandeis.edu

## Abstract

In Nature, the embryogenesis process proceeds from a single fertilized cell through division, migration, specialization and apoptosis. Although a lot is known about development, we still have a long way to go from theories of pattern formation towards understanding the intelligence within an unsupervised manufacturing process which robustly assembles complex biological forms.

Our approach has been to co-evolve bodies and brains in simulation and then convert them into reality using commercial manufacturing technology. I will review several generations of robots which were automatically designed using co-evolutionary techniques. The goal has been the fully automated design and construction of artificial lifeforms.

The first generation was based on genetic programming and a simulation of LEGO rod adhesion. The second generation used direct evolution on a iterative simulation of truss structures and used 3D printing for the output. A third generation was based on generative representations using L-systems.

In each of these cases, we assumed a perfect factory which could accept an evolved specification and then manufacture the desired result. In reality, there is no perfect factory, except for the science fiction Star Trek replicator. All manufacturing and assembly systems are subject to error. Each primitive manufacturing action results not in a deterministic new state, but a probability distribution of outcomes.

In later work, we replaced the idea of a perfect factory with one subject to noise and error. Even the smallest bit of error ruins the outcome of deterministic construction plans. We first evolved construction plans which could overcome errors through redundancy, and then this led to a new model for machine embryogenesis as a process which continuously optimizes assembly processes in a game against Nature.

## A review of one approach to bottom up assembly of minimal life

### Abstract

When seeking to assemble minimal life from the bottom up in wet carbon chemistry, the critical properties of life apparently emerge from the interconnected functions of three subsystems: information, metabolism and container. Such interconnected supramolecular systems, so-called protocells, are under the right circumstances able to mimic the main functions of a living cell although in a very simplified manner<sup>1</sup>.

Seeking to create minimal life from the top down leads us to a somewhat different picture, where construction of synthetic / streamlined genomes become the critical scientific issue<sup>2,3</sup>. How to integrate the knowledge we obtain from the top down- and the bottom up approaches is a great challenge for our and related communities<sup>4,5</sup> and a good problem to discuss at this meeting.

In technical terms, our bottom up team explores ruthenium-based photocatalysis as metabolism, fatty acids vesicles, oil droplets and reverse micelles as containers and lipophilic XNA as minimal informational systems<sup>6,7</sup>. Based on our experimental, computational and theoretical work we review protocell feeding, growth, division, motility, and information controlled metabolic production of containers<sup>8,9,10,11</sup>.

Finally, we demonstrate preliminary integration of biochemical- and microelectromechanical (MEMS) systems where life-like information processing and material production occur and interact in different media<sup>12,13</sup> and as such form an exciting frontier for the study of artificial life.

## Abstract

Computation is defining trait of biological systems and a broad framework that captures the complex adaptive nature of molecules, cells and organisms. Computation is also at the core of the genotype-phenotype mapping, since it provides a natural framework to define function in a self-consistent way. The study of existing biological systems (from signalling cascades to ant colonies or brains) as well as the evolution of synthetic *in silico* networks performing computations reveals a number of nontrivial patterns of organization, sometimes in clear conflict with standard view of engineering or optimization. In spite of our increasing knowledge, there is a lack of a theoretical framework where computation and its possible forms is integrated within a general picture. Synthetic biology provides a new avenue where engineered molecular circuits can be implemented to perform non-standard computations. Here we review recent advances in the domain of multicellular synthetic computing and suggest a potential morphospace of computational systems including both standard and non-standard approximations.

## Introduction

Computation in nature is a fascinating and yet difficult topic. Biological systems perform computations as they gather information and process it in order to respond to environmental cues. Computation is in fact one formal way of capturing functionality in a well defined fashion (1), (2). Computation has also become a key aspect within the emergent field of synthetic biology (for a recent review, see (19)). This field allows to construct completely new molecular and cellular structures able to perform artificial computations (3).

Cells can be engineered in order to behave as autonomous, potentially programmable computing devices. These biocomputing devices would be able to perform complex tasks and designed for a wide range of applications, including bioremediation, food production or biomedicine (4). How to make these systems reusable and scalable is a major problem, but new approaches involving non-standard forms of computing have been able to overcome some key difficulties (5). They define novel ways of computing using living matter and suggest potential scenarios to outline a general framework to unify the landscape of computational structures, both in the natural and artificial realms.

Figure 1: Computation occurs in natural systems in many different systems and spanning multiple scales. This include immune networks, social insect colonies, brains or some social amoebae.

In order to use computation as a unifying framework where biological complexity and its evolutionary dynamics can be suitably integrated, some formalism is needed. One possibility is to consider classical models of computation. Turing's formalization of computations in terms of machines with a number of internal states provides a powerful framework where -in principle- any potential form of computation could be described (6). The fact that some particular macromolecular systems, such as ribosomes act pretty much as Turing-like nanomachines (reading a "tape" defined by the messenger RNA, creating an output chain of aminoacids and starting and ending the process by means of detecting given sequences) seems to support this picture. Such avenue has been successfully taken by some researchers (7) proving the viability of making molecular computations close to finite automata. However, as pointed out by Melanie Mitchell (8) there is a range of biological systems, from immune net-

works to ant colonies or even plants, where computations occur and yet seem to escape from being fully captured by classical, Turing-like formal approaches to computation.

The special features shown by information-processing systems in biology have been recognized for decades. Many of them have to do with special ways of treating given computational tasks in a parallel way and using the internal dynamical features characteristic of each system. Task allocation in ants, for example, can be favoured in some cases by means of colony-level oscillations which seem in principle inappropriate for dealing with colony needs. Simple models of ant dynamics based on a neuron-like mapping between ant states and formal neurons have been very useful in this context. In particular, it has been shown that oscillations actually favour an optimal task fulfilment that is not possible if a constant, average activity level were at work (9), see also (10).

Similarly, other properties exhibited by complex biological machines strongly depart from standard engineering-based principles. One such principle is the robust behavior based on redundancy. Here two identical components of the system making the same function can replace each other in case of failure. Redundancy is thus the intuitive (although sometimes expensive) solution to the problem of failure. However, it has been shown that in many cases (may be in most cases) robust behavior is not obtained from redundant structures. Instead, it seems to be a consequence of so called degeneracy (11), (12), (13). It can be defined as the capacity of elements of a given system that are structurally different to perform the same function or yield the same output. This ubiquitous feature appears to be present in many different systems and scales. Modeling *in silico* evolved circuits performing computations under selection for robust behavior (14) reveal that robustness is achieved through degeneracy, but the underlying mechanistic explanation escapes from our intuition. Degeneracy implies a novel concept beyond standard engineering, suggesting that new forms of thinking might be required.

How can we go beyond the limits imposed by real systems, which are the result of evolution and might be difficult to fully characterize? Similarly, how can we test existing theories and try novel ones if they are sometimes difficult to compare with their real counterparts? The field of synthetic biology seems to provide the best scenario for designing novel computational systems *in vivo* whereas non-standard forms of computation are used as alternatives to engineering-inspired metaphors. Here we present some of these results and suggest a potential framework to define a space of computational designs that includes existing natural and artificial systems as well as engineered, artificial ones.

### Logic gates from gene circuits

One way of creating synthetic biological circuits performing predefined logic operations is based on engineering genetic

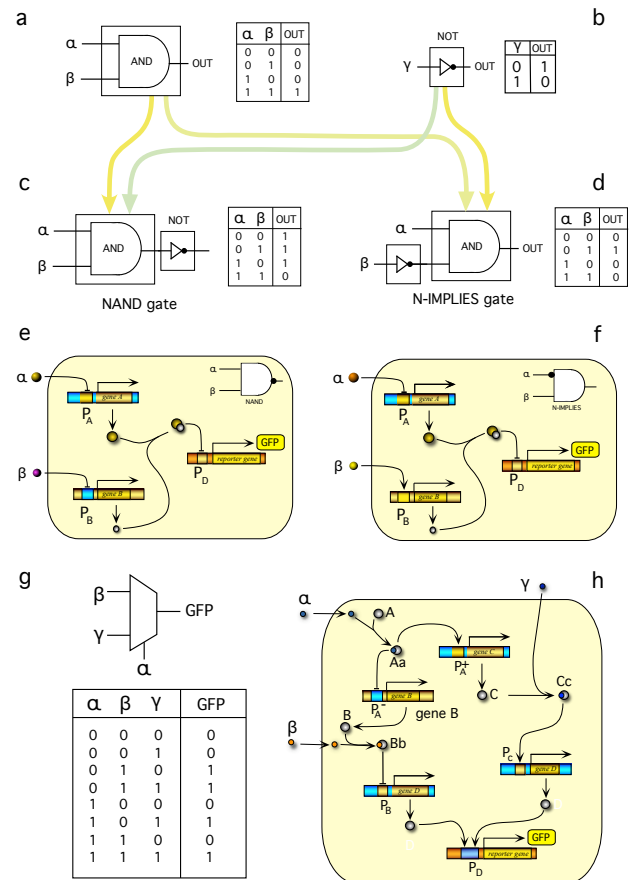

Figure 2: Logic gates and switches of different types can be obtained by engineering cellular and/or molecular systems. Examples would include (a) the AND and (b) the NOT gates, from which a NAND gate (c) or a N-IMPLIES gate (d) can be obtained through combination. In (e) and (f) we illustrate these two examples through a hypothetical gene regulatory system (the inset pictures are the compact representation of the gates).

regulatory systems. In figure (2) we show some examples of logic gates that can be implemented by using available genetic components and their interactions. Such circuits are obtained by means of standard genetic engineering techniques and the components can actually come from different, completely unrelated species, which can mix together genes from viruses, bacteria or mammals. Typically these engineered circuits are built within plasmids, i. e. closed chains of DNA defining genetic information physically separated from the chromosomal DNA. A different strategy involves using appropriate gene. In figure 2a we illustrate this by means of two basic examples and their genetic counterparts (other implementations are also possible). In our example (e) the NAND gate is obtained by using a molecular complex formed by two different proteins which repress the

Figure 3: A genetic toolkit (central line) can be used to engineer cellular computations. The toolkit might include all sorts of regulatory elements and reporters. The standard approach is putting together within a single cell, where all regulations take place. Alternatively, a library of different engineered cells can be created, thus defining a cellular consortia (top diagrams).

expression of a so called reporter gene (here GFP=green fluorescent protein) which generates, when activated, a fluorescent signal.

These examples illustrate the standard approach of electronic design based on combinatorial logic. In principle, every circuits could be designed in this way. However, a major difficulty emerges here: in electronics, every wire is defined in terms of a conducting piece of material, which is always the same. When dealing with cellular engineered systems, where molecules share the same medium where they are mixed, identity becomes a problem. In a cell, every wire needs to be a different molecule to properly connect different elements or cells. Because the liquid nature of the medium where computations need to occur, the spatial insulation of wires that is assumed in electronics is no longer satisfied. As a consequence, each wire needs to be implemented by using a different molecular carrier and the chemical diversity of constructs rapidly grows. This is illustrated in figure 1g-h by the so called multiplexor, widely used in electronic designs. This is a 3-input, one-output system where a given signal "selects" one of the two inputs. In principle a synthetic genetic network implementing a MUX circuit can be designed (an example shown in figure 1h) using a single cell

implementation. Although such circuit can be constructed (15) it is a hard task, with no hope of being re-used as part of a larger system (as it occurs in electronics).

To sum up, the combinatorial approach can lead to a nightmare when dealing with an experimental design, since the properties of each carrier and how it interacts with other can be very different and difficult to predict. Additionally, one goal of the field is to have engineered systems capable of extensive reuse of available parts in such a way that a LEGO-like system is at work. Both premises are basic requirements for reaching the computational complexity for achieving autonomous machines able to make decisions in a biological context. Only recently a general approach, based on engineering several cell types, has been successfully obtained.

### Cellular consortia: division of labor

One way of dealing with the wiring problem is considering alternative ways of avoiding the mixing of molecular carriers that seems inevitable within the cell cytoplasm. Spatial segregation of the basic components provides one easy way of dealing with computation avoiding molecular mixing. Although the explicit use of spatial locations is one possibility

(see for example (16) a simpler scenario involves using cellular consortia, namely a population of cells having different types of engineering designs. In such scenario, a library of different cell types, each one having a different subset of genetic components, is build out of a collection of molecular components. This is schematically displayed in figure 3, where we show three different ways of combining them within single or multicellular constructs.

Here different cell "types" are indicated as CT1, CT2, etc. A standard consortium (top left) is obtained by splitting some of the elements from the toolkit between cells. Communication is then also introduced, so that a sender and a receiver cell are usually designed, although feedbacks are also introduced in most designs. A reporter cell is present (here CT2) which will (1) or will not (0) express a target molecule. This type of consortium has been used in many different contexts. In particular, using two cell types it was possible to artificially recreate predator-prey systems (Lotka-Volterra dynamics), mutualistic ensembles (hypercycle-like systems) or parasitic organizations. Extensions of these include multispecies ecosystems where different groups of cells belonging to different kingdoms are involved (17). Once again, however, the resulting synthetic cells are hard to reuse to obtain other types of computations. An alternative approach requires breaking some predefined rules.

In any standard circuit design, the truth table defines the input-output relation between incoming sets of signals and the resulting outputs. The outputs are placed in given locations of the circuit and it makes sense that this is the case. Let us limit ourselves here to a single-output system. That means that there is an output unit where the final result of the information processing is released. What happens if we free ourselves from such (rather reasonable) assumption? The view of a computational device as being implemented by a circuit that clearly differentiates between input, processing and output units seems too obvious to replace it by some other paradigm. But there is actually one solution that emerges from not forcing that assumption to be true. Instead, more than a cell type is able to respond as output element.

## Distributed computation

Here we introduce our basic model approach to synthetic computation. We will use a Boolean approximation, thus confining our approximation to the digital domain. Our state space will be described by a set  $\Sigma = \{0, 1\}$ . Although this is in principle a limitation, many relevant cellular computations seem to take place by means of genetic switches. Such switches effectively define binary states with low and high levels of gene expression. A given functionality will be described as an input string  $\mathbf{I}$ , namely an element of

$$\Sigma^N = \underbrace{\{0, 1\} \times \dots \times \{0, 1\}}_n \quad (1)$$

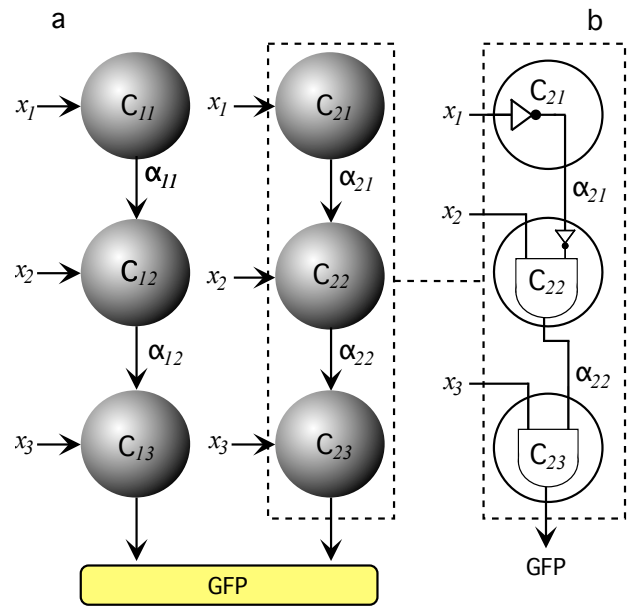

Figure 4: The general architecture used here to generate our circuits using distributed computation, as defined in the text. A feed-forward structure (a) is assumed as the basic scaffold, with a number of input signals that affect separated arrays of communicating cells (gray spheres). Each cell implements a given logic function (b). All columns end up in a reporter cell, but several reporter cells can be present, since each column is segregated from others, thus removing potential cross-talks.

It will indicate, in our framework, a string of absent (0) or present (1) chemical signals.

The functional trait to be implemented is formally defined as a Boolean function  $\phi_i$  with  $N$  input signals and a single output. Formally, this reads:

$$\phi_i : \Sigma^N \longrightarrow \Sigma \quad (2)$$

Two particularly relevant subsets of Boolean functions are the one input-one output gates, i. e. the set  $\mathcal{G}^{(1,1)} = \{NOT, Id\}$  (the negation and identity functions, respectively) and the  $2^4$  two-input logic gates defining the set  $\mathcal{G}^{(2,1)} = \{g_j\}$  where  $g_j$  is a mapping

$$g_j : \Sigma^2 \longrightarrow \Sigma \quad (3)$$

(represented by a simple table). Standard functions include OR, AND and their "inverse", i. e. NOR and NAND.

Our approach to a general design of complex computational circuits (5) is based on two general assumptions, to be translated into a basic circuit design (fig 4). First, we limit ourselves to a feed-forward network where each node is one type of engineered cell from the library. Each link means the existence of a molecular connection, i. e. a diffusible

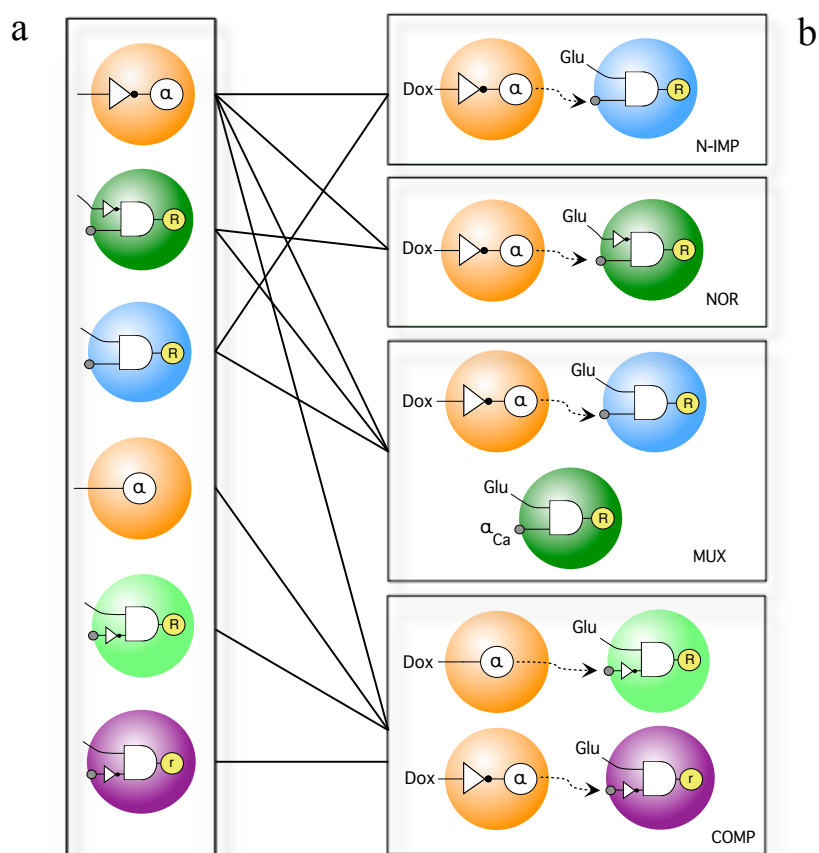

Figure 5: Combinatorial design of multicellular consortia using our distributed computation method. Here in (a) we sketch some basic engineered cell types (implemented on yeast cells) and several examples (b) of combinations performing given functions. Many other circuits can also be constructed using this library or small extensions of it.

wire molecule. Secondly, several cell types can incorporate the gene responsible for the output molecule (GFP). Once a given Boolean table is chosen, an evolutionary algorithm is applied to the basic wiring structure, which explores the landscape of potential networks implementing the desired function (3). The algorithm searches over the space of basic functions, wiring configurations and other constraints. Once a given network is found, standard rules of circuit minimization are applied in order to obtain the minimal circuit solving the problem by means of distributed computation.

What are the results of this method? Along with this evolutionary algorithm, the theoretical analysis demonstrates that it is possible to minimize the number of required cells and wires using the distributed output assumption combined with a small library of cells implementing only the AND and the inverted Implies gates (N-IMPLIES). Despite this combination of gates are not usually used in circuit designs they

define a functional complete set, i.e. any arbitrary Boolean function can be implemented only combining this two gates. In some embodiments, these gates can be simplified and replaced by the IDENTITY and the NOT gates respectively allowing for a circuit simplification. Furthermore, the wiring pattern of connections is restricted, i.e. different circuits can involve different number of cells and wires but all cells only respond to an external input and to single diffusible molecule acting as a wire according with the specific logic function implemented, i.e. AND or N-IMPLIES, independently on the circuit complexity.

Using yeast cells as the model organism to implement our cell library (following the theoretical predictions) it was possible to construct, by combining different cell types, all kinds of simple gates (figure 5) but also complex circuits. As an illustration of the enormous simplification of circuit complexity that is derived from our approach, in figure 5 we

can see that the MUX circuit can be obtained by combining three cells from the library (it can also be done with only two). Similarly, much more complex circuits, such as a binary adder (figure 5) was also obtained. As we can see from the two complex circuits, the assumption of distributed computation makes possible to actually split the circuit in different segregated (and thus disconnected) parts. Once again, this is in deep contrast with the standard view of electronics.

A final result concerns the predicted types of cell-cell interactions that is predicted by the evolutionary algorithm. Using the MUX circuit as the basic reference, we run the algorithm in such a way that many different circuits were obtained, all consistently implementing the multiplexer. In figure 6 we display a graph summarizing two relevant pieces of information. The nodes are the basic gates implemented by individual cells. Their size here is proportional to their frequency in the evolved circuits. We can see that there are wide differences between different logic components. Secondly, the weighted links between different gates indicate how frequently two given gates appeared connected within a given solution. The resulting network illustrates once again the nonstandard character of our solutions. The first lesson is that, although it is known that NOR and NAND gates could be in principle used as the single logic elements to implement any logic circuit (18) this solution is largely ignored by the algorithm. Secondly, the N-IMPLIES function, which was successfully used in (5) seems to be a key component in most solutions. Since the N-IMPLIES gate is not a standard component in electronics but seems to be very important here, this suggests that some design principles used in synthetic biology might need to be revisited.

The potential power of distributed computation as described above is illustrated by noticing that even a small number of engineered cell types makes possible to create hundreds of synthetic circuits (5) and thus a huge potential array of functions. Adding wires makes the combinatorial power of the system to rapidly increase in orders of magnitude the number of potential circuits, which are easily achieved thanks to the enormous capacity for tinkering and combination.

## Discussion

Synthetic biology has been rapidly gaining relevance and potential as novel techniques are getting incorporated to the field and new applications start to emerge (?), (20), (21). Our view of the area in terms of computation is simply a way of addressing the combinatorial potential of functional circuits in a very broad way. Such view allows to properly address some of the key problems in the field, namely wiring constraints and real combinatorial design. Our recent work indicates that by removing the assumption of specified output units, by allowing the output to be distributed over multiple cell types, low-wiring, combinatorial circuits can be obtained.

Figure 6: The weighted network obtained for many different evaluations of the evolutionary algorithm searching for multicellular MUX networks.

The previous results are encouraging in two different ways. On the one hand, given the truly combinatorial potential of the method, hundreds of possible synthetic designs can now be constructed. The method allows to predict possible ways of building minimal circuits and thus adapt the required result to experimental constraints. But it also opens an interesting framework to approach more general questions. Our method shows that an unexpected way of solving computational problems can be obtained.

The resulting solutions are counterintuitive and reveal an alternative form of actually achieving the right computation through cellular consortia that can be disconnected into several pieces. Moreover, the results might be more general. For convenience, we have presented our work in terms of cellular consortia, where the basic, spatially defined units are cells. But it might well be the case that other scenarios, such as sub-cellular structures, also fit within our framework. Different cellular compartments could in principle perform parts of the computational processing required to implement a given function in a distributed manner. Since biology tends to make possible everything that can be imagined under reasonable terms, we predict that the kind of computations presented here are likely to be found in living systems.

It is also interesting to notice that reliable computation at low wiring cost has been achieved through a method where autonomous parts emerge as part of the solution. Given a function to be implemented, the architecture of the resulting design involves different parts contributing to the overall computation but essentially independent. This result suggests that the evolved circuits might actually display a high degree of robustness, and preliminary results seem to con-

Figure 7: A toy space of computations where the three axes include the presence of spatial segregation, degree of multicellularity and to what extent the computation is sequential or parallel. Several well known examples are located at roughly representative locations. Here LV= Lotka-Volterra synthetic ecosystem, HC=mutualistic synthetic system, NAND, NOR chips: small chips constituted by only NAND and NOR gates, widely used as basic building blocks in many electronic designs; FPGAs: field programmable arrays.

firm this point.

Finally, our results also introduce an additional layer of complexity within biological computation. If we define an imaginary, qualitative space of computational structures where the number of different cells and the presence of space define two axes, a third one would be the relative importance of distributed computation as defined here (in terms of the output). A tentative (and by no means exhaustive) picture of this space is provided in figure 7. In this space, we have allocated different known systems that differ in their computational power and how it works. Our distributed computation approach defines, a corner of this diagram (encircled, right sphere). The three axes are intended to capture three relevant features of computational systems. These are: (a) degree of parallelism, (b) diversity of units involved (cells for our engineered systems but can be ant castes or electronic components in other contexts) and (c) spatial embedding, meaning how relevant is the spatial distribution of the agents while performing computations.

This is a largely unexplored space, where spatial degrees of freedom can help to further simplify our implementation and simultaneously increase our combinatorial power (unpublished results). Moreover, it is possible to show that a limit case of our implementation, where all cells in the consortia are actually disconnected among them, can successfully be implemented too. Many open questions emerge from this work, but it also provides an elegant and promising

scenario where many relevant questions will be testable, including potentially unexplored forms of computation, their robustness and evolution.

## Acknowledgements

## Abstract

Biological systems are insanely complicated. If we look at the details of plant growth, of the vertebrate adaptive immune system, of bacterial horizontal gene transfer (to pick three areas with which I have a soupçon of familiarity), it is *all* insanely complicated, on every level, from top to bottom. When a feature is this ubiquitous, it may just be necessary. It is at least telling us something important.

One of the guiding principles of ALife is studying, understanding, and creating life *from the bottom up*. Since our only current exemplar, biological life, is insanely complicated, even at the bottom, what does this tell us about *in silico* implementations?

Everything we are taught in Software Engineering is about reducing, constraining, containing, and managing complexity. Well-defined small stable interfaces. Formally specified requirements. Rigorous development of correct code. And all this known and documented before the code is deployed in the field.

Life however exhibits open-ended evolution, continual novelty: not only new organisms, but new species, new families, new phyla, new kinds of life. Evolution evolves. The code of life writes itself.

Object-oriented agent-based simulations running inside an evolutionary algorithm, no matter how bio-inspired the genetic operators, nor how bio-inspired the developmental stage, are *closed*. They cannot escape their small pre-specified box in possibility space. They cannot exhibit open-ended evolution. If we want life *in silico*, we have to allow the code to write itself.

I am not suggesting that we throw up our hands in despair, pour assembly language into a big bucket and just let it trample all over itself, in the hope that life will emerge after several billion CPU years. We can use bio-inspiration at the whole simulation level, to develop code that can self-adapt and self-modify in ways plausibly analogous to bio-evolutionary processes. Hand-in-hand with our sophisticated understanding of biology, we need to use more sophisticated computer science, including self-modification through computational reflection.

### Abstract

With the first three hours of development, the *Drosophila* embryo establishes a precise pattern of transcription factors that divides the blastoderm into groups of cells destined to form different organs and tissues in the adult. Along the dorsal ventral axis, the first and perhaps most important of these cell fate decisions is the establishment of mesoderm controlled by expression of the Twist and Snail transcription factors. These cell fate decisions are immediately translated in changes in the shapes and physical properties of the 800 mesodermal cells and result in the formation of the furrow that translocates them to the interior. Although at the cellular level these changes involve a re-organization of the cytoskeleton, adhesion and motor activities to achieve distinct shape we are interested in the underlying physical parameters that govern behavior.

In my talk I will discuss the relationship between the initial transcription profiles and a novel pulsating reorganization of the Actin/Myosin cytoskeleton in the apical region of cells that will make the ventral furrow. We show that the resultant contractile pulses drive cell shape changes in the entire mesodermal primordium. The individual contractions appear to be unpolarized but they result in polarized wedge-like constrictions because global tension in the sheet is polarized along the AP axis. We analyze the force distributions in the mesodermal primordia using a combination of genetics and RNAi to lower adhesive strengths between cells, and laser dissections to locally disrupt the cytoskeleton.

We have developed analytical tools that allow tracking surface areas and volumes of all 800 mesodermal cells during the process of furrow formation. We find that cell volume is essentially constant during the process and that global cell shape changes are pulsed in synchrony with the Actin/Myosin contractions in the apical surface. We envision that force generated apically is transmitted over large distances by the non-compressible nature of the cytoplasm and suggest that similar mechanism that may underlie many morphogenetic movements.

## Abstract

Knowing every single component of a given biological system is not enough to understand the complexity of the system but rather it becomes crucial to understand how these components interact with each others. It is not only important the knowledge of genes and proteins, but also knowing their structures and primarily the laws and parameters governing their dynamics, which is often unknown and impossible to measure directly. The *Gene Regulatory Networks* explain exactly how a genomic sequence encodes the regulation of expression of sets of genes, which progressively generate developmental patterns, and execute the construction of multiple states of differentiation. Their main aim is to represent the regulation rules underlying the gene expression. In this work we have designed the CMA-ES algorithm to infer the parameters in the S-system model of a gene regulatory network. This model is a well-known mathematical framework whose structure is rich enough to capture many relevant biological details, and it can model more complicated genetic network behaviour. CMA-ES has been compared against 7 state-of-the-art algorithms to evaluate its efficiency and its robustness. From a general point of view, it seems clear how CMA-ES is able to estimate in a better way the target parameters with respect to the state-of-the-art methods, either in terms of success rate or in terms of Euclidean distance. Finally, this research paper includes a study on the convergence of CMA-ES through Time-To-Target plots, which are a way to characterize the running time of stochastic algorithms; and a global sensitivity analysis method, the Morris algorithm.

## Introduction

In the past few years studying how a system interacts with the environment, or how simple components effect the global behaviour of a given system, or even how parts of a system interact with each others has been the main and most challenging issue in many research areas. Many problems in science and engineering are often hard to solve mainly because of the difficulty in understanding their indirect causes and effects, which are not related in an obvious way. Assessing all the single parts of a structure, or knowing all single components of a given system is not enough to determine and understand the complexity of system, although we need to know how these objects interact. It is also well known that

the information on the complex molecular features are contained in the genome of the organism, but is not clear what are the codes and mechanisms that translate the sequences into structures and functions. For example, from systems biology point of view, it is not only important a knowledge of genes and proteins, but it is of primary importance understanding their structures, dynamics, and how their parameters influence the global dynamics: such parameters are unknown and often impossible to measure directly. Moreover, studying dynamic properties of a biological system is not only very important to gain a deep understanding of biological processes, but also to develop efficient treatments against diseases. In systems biology *reverse engineering* the processes can be regarded as a central part of the discipline itself (Lee, 2005). Reverse engineering can be considered as a process from which is possible to infer structural and dynamics features of a given system from external observations and relevant knowledge. Thanks to that, today reverse engineering techniques play a central role in systems biology (Csete and Doyle, 2002; D’haeseleer et al., 2000). The main focus in reverse engineering field is the identification of genetic networks (Cho et al., 2007) in order to learn how transcription factors are connected to genes (the determination of the interactions between all genes and understanding of the regulatory networks are crucial to identify and develop novel drugs), and understand the gene expression profile that is a major issue in computational biology. In other words, reverse engineering can help us to answer questions as: (1) what are the functions of this gene? (2) which genes regulate this gene? (3) how several genes interact? (4) which genes are responsible for this disease? (5) which drugs will treat this disease? Of course, a method to interpret these answers is needed, in order to enhance our learning of living organisms. *Gene Regulatory Networks* (GRNs) explain exactly in which way genomic sequences encode the regulation of expression of sets of genes that progressively generate developmental patterns and execute the construction of multiple states of differentiation (Davidson and Levin, 2005). The main aim of GRN is to represent the regulation rules underlying the gene expression. Albeit the study of GRNs

nowadays is made easier thanks to the advances of new technologies however the solution to the problem is not trivial due to the enormously large space of the unknown parameters. In the last years several reverse engineering methodologies based on evolutionary algorithms have been presented (Kabir et al., 2010; Kikuchi et al., 2003; Noman and Iba, 2007), which are more suitable to effectively and efficiently reconstruct the networks in a given dynamic model. It is well known as evolutionary algorithms work better than standard methods when the problem to solve is nonlinear, and therefore or no solution is known a priori, or it is impossible to be analytically solved. The great advantage of the evolutionary approaches on these tasks is own their applicability to almost any models where mathematical analysis and reversing is unavailable or inefficient. A good comparative study among evolutionary algorithms in gene regulatory network can be found in (Schlitt and Brazma, 2007). In this research work, we present a new approach to infer parameters of a gene regulatory network from time-series gene expression data using *S-system* model (Irvine and Savageau, 1990). For this kind of task, one of the best population-based optimization algorithms has been used as learning paradigm: *Covariance Matrix Adaptation Evolution Strategy* (CMA-ES) (Hansen and Ostermeier, 2001).

### The S-system model for gene expression

Developing accurate computational and mathematical models is needed to study the response of the gene regulation and the gene sets with respect to their specific dynamics (many important cell functions are largely determined by dynamic processes of biochemical networks). Therefore, using mathematical models for the analysis of metabolic and regulatory pathways may contribute to a better understanding of the behaviour of metabolic processes. These models, once built, can be used to predict the behaviour of the organism under certain conditions (Sirbu et al., 2010), it has been also postulated that, once inferred the basic mechanisms of life, it should be (theoretically) possible to create synthetic organisms (Barrett et al., 2006). Of course, the choice of the model to use depends by how much information we try to capture: more information a model trying to learn - more parameters need to be inferred - more complex becomes the model. Nowadays, there exist several types of models in literature that describe a gene regulatory network, as: *Boolean networks* (D’haeseleer et al., 2000; Akutsu et al., 1999); *Bayesian networks* (Friedman et al., 2000), and *methods based on a steady-state description* (Tegner et al., 2003). Unfortunately, the main drawback of these models is that the gene expression is represented only in the two extreme levels, and therefore all genes are mapped only in a binary state: *on* (1) or *off* (0). This disadvantage makes limited use of such models since the real gene expression levels tend to be continuous rather than binary. An other drawback is also given from their not ability to capture the non-

linear gene regulations, typical feature of the gene regulatory networks. To overcome this limitation, models based on *ordinary differential equations* (Chen et al., 1999) have been designed, which represent a very powerful and flexible model to describe complex relations among more components. One of the most popular and studied approaches, based on ODE, is the *S-system* model, whose structure is rich enough to capture many relevant biological dynamics, and it can models much more complicated GRN behaviour (Wessels et al., 2001). A comprehensive interesting comparative study on the three most used continuous systems based on ordinary differential equations has been made in (Swain et al., 2010) (*S-system*, *artificial neural network* (Vohradsky, 2001), and *general rate law of transcription* (Mendes et al., 2003)), where the advantages and disadvantages of each deterministic model used for modelling gene regulatory networks have been reported. In the last decades, inferring gene regulatory networks from time-series data has attracted a lot of attentions by many researchers in systems biology. It is then important to develop proper models that incorporate a suitable compromise among different requirements, as e.g. computational complexity, the ability to capture nonlinear gene regulations and the ability to handle noisy data. Moreover, it is also able to model much more complicated GRN behaviour (Wessels et al., 2001), and therefore it presents a good compromise between accuracy and mathematical flexibility. The *S-system* model is a type of power-law formalism used to model molecular networks, whose expression rates are described as the difference between the activation and degradation terms of a gene product. It is formally defined as a set of non-linear ordinary differential equations of the form:

$$\frac{dX_i}{dt} = \alpha_i \prod_{j=1}^n X_j^{g_{ij}} - \beta_i \prod_{j=1}^n X_j^{h_{ij}}, \quad (1)$$

where  $n$  is the number of the genes;  $X_i$  is the expression level of the  $i$ -th gene; the exponential parameters  $g_{ij}$  e  $h_{ij}$  represent the effective interaction of  $X_j$  to  $X_i$ . In equation (1), the first term represents all influences that increase  $X_i$ , whilst the second term the ones that decrease  $X_i$ : if  $X_j$  has a positive exponent it means that it has a positive correlation on the aggregation process, whilst if it is negative then the genes are negatively correlated. Of course, if the exponent is zero then there not exist any influence on the aggregation process. From biochemical engineering point of view, the non-negative parameters  $\alpha_i, \beta_i \in [R_l, R_u]$  are called *rate constants*, whereas the real value exponents  $g_{ij}, h_{ij} \in [K_l, K_u]$  are referred to as *kinetic orders*. The aim on the *S-system* model is inferring the set of parameters  $\Omega = \{\alpha_i, \beta_i, g_{ij}, h_{ij}\}$ , such that the fitness function is minimized. Is easy to see how extracting the parameters  $\Omega$  in a genetic network with  $n$  genes is not trivial task due to the high dimensionality of the problem:  $2n(n+1)$  parameters indeed must be inferred. Obviously, the difficulty

of the problem increases by how much information need to be captured. To overcome this limitation and facilitate the regression task a *decoupled variant* of the model has been proposed (Kimura et al., 2005; Noman and Iba, 2006; Vilela et al., 2008a), which reduces the problem in  $n$  sub problems. Through this decomposition strategy, the original optimization problem is divided into  $n$  sub-problems where in any gene  $i$  the parameter values  $(\alpha_i, \beta_i, g_{ij}, h_{ij})$  are individually estimated to attempt to capture the dynamics of the own gene. In this way, the original problem of  $2n(n+1)$  dimensional is reduced in  $n$  sub problems each of  $2(n+1)$  dimension. Thus, in the  $i$ -th sub-problem the expression level of the gene  $i$  is computed by the following ordinary differential equation:

$$\frac{dX_i}{dt} = \alpha_i \prod_{j=1}^N Y_j^{g_{ij}} - \beta_i \prod_{j=1}^N Y_j^{h_{ij}}, \quad (2)$$

where:

$$Y_j = \begin{cases} X_j, & \text{if } i = j \\ \hat{X}_j, & \text{otherwise,} \end{cases}$$

with  $X_j$  computed solving the differential equation (2); and  $\hat{X}_j$  estimated directly from experimentally observed time-series data using differential equation (1). Estimating the inferred set of the parameters is usually evaluated by the *Mean Squared Error* (MSE) between the experimentally observed expression levels, and the ones computed solving the system of equation (1). Therefore, the optimization task is inferring the parameters  $\Omega$  in decoupled form in order to minimize MSE.

### The CMA-ES algorithm

To attempt to inferring the set of parameters of a genetic network using the S-system model, we have adopted the CMA-ES algorithm (Hansen and Ostermeier, 2001), one of the best population-based optimization algorithms that is very suitable primarily on non-linear and non-convex optimization task. Since CMA-ES algorithm is well known inside the evolutionary computation community, in this section we give a short description on its main features. It is a  $(1+1)$  elitist evolutionary strategy that generates candidate solutions by adapting a covariance matrix  $C$ , such that steps promising large fitness progress are sampled more often. Conversely to other self-adaptive evolutionary algorithms, CMA-ES adapts the covariance matrix, at generation  $g$ , by additive updates of the form  $C^{(g)} = \alpha C^{(g-1)} + \beta V^{(g-1)}$ , where  $V^{(g-1)} \in \mathbb{R}^{n \times n}$  is positive definite and  $\alpha, \beta \in R_0^+$  are weighting factors. Let  $v^{(g-1)} \in \mathbb{R}$  a promising mutation step, to increase the probability of sampling  $v^{(g-1)}$  in the next generation, the rank-one update is performed in the equation:  $C^{(g)} = \alpha C^{(g-1)} + \beta v^{(g-1)} v^{(g-1)T}$ . This update strategy shifts the mutation distribution towards the Gaussian with highest probability of generating  $v^{(g-1)}$ . The

CMA-ES algorithm is based on three main procedures: (1) *main loop*, (2) *step size updating procedure*, and (3) *covariance matrix updating strategy*. The CMA-ES main loop follows the classical  $(1+1)$  scheme, where the offspring  $x_{\text{offspring}}$  replaces the parent  $x_{\text{parent}}$  if its fitness value is better. Successively, the algorithm updates the step size, which is based on the heuristic that increases it if the success rate is high, and reducing it otherwise. The procedure performs an update based on a binary variable  $(\lambda_{\text{succ}})$ , which is set to 1 if  $f(x_{\text{offspring}}) \leq f(x_{\text{parent}})$ , with learning parameter  $c_p \in (0, 1]$  using a target success rate  $p_{\text{succ}}^{\text{target}}$ . If  $p_{\text{succ}} > p_{\text{succ}}^{\text{target}}$  the argument is greater then zero and the step increased; if  $p_{\text{succ}} < p_{\text{succ}}^{\text{target}}$ , the argument is smaller than zero and the step size is decreased otherwise it remains unchanged. Finally, the update of the covariance matrix and the evolution path ( $p_c$ ) takes place if  $f(x_{\text{offspring}}) \leq f(x_{\text{parent}})$ , and it depends on the values of  $p_{\text{succ}}$ ; if  $p_{\text{succ}}$  is high the update of  $p_c$  is blocked in order to prevent a fast increase of the  $C$  axis when the step size is low, otherwise the update occurs by an exponential smoothing. The new covariance matrix is a weighted mean of the old matrix and the outer product  $p_c p_c^T$ . Major details on CMA-ES can be found in (Auger and Hansen, 2005; Hansen and Ostermeier, 2001; Cutello et al., 2010).

### Results

For our experiments we have used the classical artificial genetic networks that include an overall of 5 different instances: 2 instances with 2 genes (Vilela et al., 2008a), where 12 parameters need to be inferred for each; 1 instance with 4 genes (Vilela et al., 2008a) and 40 parameters to be inferred; and finally 2 artificial networks with 5 genes (Vilela et al., 2008a; Kikuchi et al., 2003; Noman and Iba, 2006), where 60 parameters must to be inferred. Of course, thanks to these experiments we are also able to evaluate the performances and efficiency of CMA-ES on this new kind of complex optimization task. Due to a limit pages we show in this section the results on the networks with 5 genes. In all experiments, we have considered the ranges where compute parameters  $(\alpha, \beta \in [R_l, R_u])$ , and  $g_{ij}, h_{ij} \in [K_l, K_u]$ , as well as initial conditions, the same ones used in the relative papers from where each instance has been taken into account. About CMA-ES algorithm, instead, we have fixed  $\mu = \lambda = 100$ , and 100 sample points; as termination criterion has been used a maximum number of fitness function evaluation fixed to  $10^8$ . Moreover, each experiment has been performed over 10 independent runs as proposed in (Vilela et al., 2008a). In the first experiments presented in this section we compare CMA-ES with the algorithm proposed in (Vilela et al., 2008a) (in the follows called *Voit's* algorithm), which is based on eigenvector optimization of a matrix formed from multiple regression equations of the linearized decoupled S-system. In these experiments we have tested CMA-ES on artificial gene networks with 2 (two in-

Table 2: CMA-ES versus state-of-the-art optimization algorithms. The comparisons have been done on a genetic network with 5 genes considering the *Euclidean distance* ( $d_{euc}$ ) as evaluation measure. In all algorithms, for each gene has been included the best computed parameters (the rate constants  $\alpha_i$ ,  $\beta_i$  and the kinetic orders  $g_{i,j}$ ,  $h_{i,j}$ ).

Table 1: Success rate (SR) obtained by CMA-ES and *Voit's* algorithm (Vilela et al., 2008a) on 10 independent runs. Both algorithms have been tested on an artificial network with 5 genes.

gene	CMA-ES	<i>Voit's</i> alg. (Vilela et al., 2008a)
$X_1$	100%	100%
$X_2$	100%	100%
$X_3$	<b>100%</b>	0%
$X_4$	100%	100%
$X_5$	100%	100%

stances – normal and rescaled), 4 (rescaled) and 5 components. For each instance three different data sets have been used. All details about the instances can be found in the relative additional material (Vilela et al., 2008b). On the

artificial genetic network with 2 genes both algorithms are comparable in term of success rate (*SR*), that is how many times the algorithm infers the parameters target. However, if we compare the results where both algorithms fail, it is possible to see as CMA-ES outperforms the compared algorithm in terms of *Euclidean distance* between the computed parameters and estimated parameters. This means that CMA-ES is able inferring the set of parameters closer to the estimated ones. The rescaled 2 genes network is, instead, equal to the normal one where however  $\alpha$  and  $\beta$  are multiplied by a constant. In this experiment, using all three data sets, CMA-ES has been found the  $\Omega$  target for each gene in all 10 runs with  $SR = 100\%$ , except for the gene  $X_2$  of the 3rd data set where  $SR = 70\%$ . The compared algorithm, instead, presents  $SR = 100\%$ , excepts for the gene  $X_2$  in the 2nd and 3rd data set, with respectively  $SR = 80\%$  and  $SR = 70\%$ . In the overall, we can say that CMA-ES outperforms the *Voit's* algorithm (Vilela et al., 2008a) in both artificial genetic networks with 2 components (in terms of

success rate and Euclidean distance). For the network instance with 4 genes, both algorithms are equivalent, since they have been able to find always the network target in all 10 runs ( $SR = 100\%$ ). About the experiments on the artificial network with 5 genes, CMA-ES and the *Voit's* algorithm have been compared on three different data sets. However, due to the limit pages we report in Table 1 only the results obtained on the 2nd data set. Inspecting the Table, is possible to see that albeit both algorithms reach a  $SR = 100\%$  for the genes  $X_1$ ,  $X_2$ ,  $X_4$ , and  $X_5$  CMA-ES is able also to inferring the estimated parameters for the gene  $X_3$  on all 10 runs ( $SR = 100\%$ ), where instead *Voit's* algorithm fails with a zero success rate. Fig. 1 shows the gene expression

Figure 1: Gene expression levels computed by CMA-ES on the artificial network with 5 genes using 100 sample points.

levels computed by CMA-ES on the second data set. Looking the Table 1 is easy to understand how these curves represent exactly the gene expression levels of the target network. These plots have been obtained with a time-series based on 100 sample points. Instead, about the experiments in order to the other two data sets, we can say that from the obtained results is clear as both algorithms are able to estimate for all genes the target parameters, with  $SR = 100\%$ , about the first data set, unlike the third data set, where CMA-ES shows best performances (in the overall) than the *Voit's* algorithm. In this last data set, CMA-ES outperforms *Voit's* Algorithm on the genes  $X_1$ ,  $X_4$  and  $X_5$  with a success rate of 100%, with respect to a success rate of 30% ( $X_1$ ), and 0% ( $X_4$  and  $X_5$ ). Only on the gene  $X_3$  CMA-ES fails over all 10 runs unlike the *Voit's* algorithm that produces a  $SR = 70\%$ . However, although CMA-ES seems not comparable to the *Voit's* algorithm for the gene  $X_3$ , if we take into account only the remaining 30% of the computed parameters by *Voit's* algorithm, where  $SR = 0\%$ , and we compare them with all ones produced by CMA-ES is possible to note how the inferred parameters by our algorithm seem better in term of Euclidean distance from the expected target parameters. To better evaluate the robustness of our proposed

algorithm on these kinds of complex optimization tasks we have compared CMA-ES with state-of-the-art algorithms on S-system models. For these new experiments the *Euclidean distance* from the estimated parameters has been chosen as evaluation measure. A new instance with 5 genes has been considered that is different from the previous one because different ranges have been used where compute  $\Omega$  parameters. For this instance, moreover, it is important to point out that CMA-ES has been tested on 100 independent runs, producing an high success rate very closer to 100%. In Table 2 we report the comparisons of CMA-ES with the state-of-the-art, where only the best results for all algorithms have been included. The algorithms compared with CMA-ES are: (1) MO-HDE (Liu and Wang, 2008), a multi-objective optimization approach based on an hybrid differential evolution; (2) coop-CE (Kimura et al., 2005), a cooperative Co-evolutionary algorithm; (3) HDE (Tsai and Wang, 2005), a hybrid differential evolution; (4) and (5) two different versions of trigonometric differential evolution ( $TDE_1$  (Noman and Iba, 2005) and  $TDE_2$  (Noman and Iba, 2006)); and finally (6) PEACE1 (Kikuchi et al., 2003) based on a Genetic algorithm. From the Table is clear as CMA-ES produces the best performances with zero Euclidean distance, whilst the best among the compared algorithms was able to reach 0.05 as Euclidean distance from the estimated parameters. The genetic algorithm is instead the one with worst performances. It is possible to claim that CMA-ES outperforms the current state-of-the-art optimization algorithms on S-system models.

### Time-To-Target Analysis

Time-To-Target plots (Aiex et al., 2002) are a method to characterize the running time of stochastic algorithms to solve a given computational optimization problem. They display the probability that a given algorithm will find a solution as good as a target within a given running time. Nowadays they are standard graphical methodologies for data analysis to compare the empirical and theoretical distributions (Aiex et al., 2002, 2007). By Time-To-Target analysis two kinds of plots are produced: *QQ*-plot with superimposed variability information, and superimposed empirical and theoretical distributions.

We ran CMA-ES on the genetic network with 5 genes, and where the success rate in inferring the set of parameters of all genes is 100%. For this kind of experiments a different termination criterion has been properly tuned: until finding the parameters target for each gene ( $SR = 100\%$ ). Because larger is the number of runs closer is the empirical distribution to the theoretical distribution, the plots presented in this section have been produced after 100 independent runs. The Fig. 2 shows the convergence process produced by CMA-ES using `tttplots.pl` on  $n = 5$  network instance. In the top plot is showed the comparisons among empirical and theoretical distributions, whilst in bottom one is showed the

Figure 2: Time-To-Target plots for the network with 5 genes.

*QQ*-plot with variability information. Looking the top plot is possible to see as the curves of the empirical and theoretical distribution are equivalent. A different behaviour instead is showed on the bottom plot; this is likely due, since CMA-ES finds in quick way the parameters target.

### Sensitivity Analysis – The Morris Method

The *Morris method* is one of the most popular models to evaluate the importance of any single parameter of a given system, showing own the main interactions between the parameters. In this method, any parameter assumes a discrete number of values chosen inside a range of variation; these values are called *levels*. Morris (Morris, 1991) has used a sensitivity analysis based on the *elementary effect* of the  $j$ -th parameter, defined as:

$$EE_j(p^*) = \frac{[f(p_1^*, \dots, p_{j-1}^*, p_j^* + \Delta, p_{j+1}^*, \dots, p_{N_p}^*) - f(p^*)]}{\Delta},$$

where  $\Delta$  is a predetermined multiple of  $1/(k-1)$  ( $k$  is the number of levels). To understand what are the parameters, which influence on the output we have performed the Morris method for the S-Systems models, with  $n = (2, 4, 5)$  genes. The obtained results are showed in Fig. 3. Two sensitivity measures,  $\mu_j$  and  $\sigma_j$ , have been evaluated for any parameter

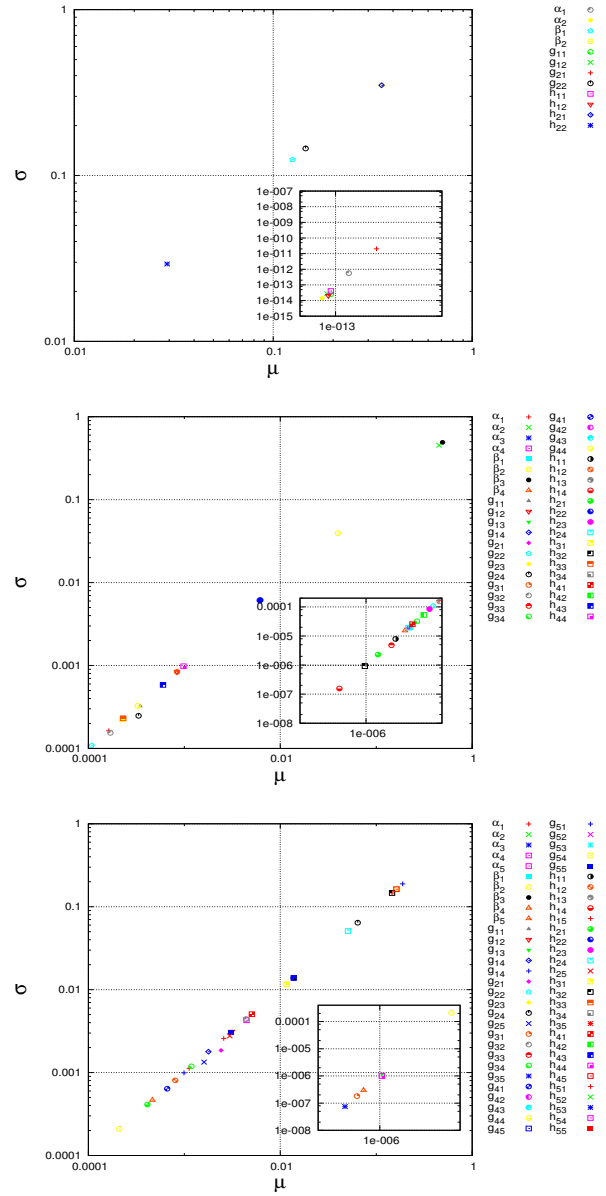

Figure 3: Sensitivity analysis by Morris method. A high value of  $\mu$  indicates a parameter with an important overall influence on the output. A high value of  $\sigma$  indicates a parameter involved in interaction with other parameters or whose effect is nonlinear. The results show high  $\mu$  and  $\sigma$  values for  $h_{21}$  and  $\beta_2$  for the GRN with N=2 genes (top plot), for  $\alpha_2$  and  $\beta_3$  for the GRN with N=4 (middle plot), for  $g_{24}$ ,  $g_{44}$ ,  $g_{51}$ ,  $h_{15}$ ,  $h_{24}$ ,  $h_{32}$ ,  $h_{45}$  for the GRN with N=5 (bottom plot).

$j$ : the first represents an estimate of the mean of the distribution of the elementary effects, whilst the last indicates its standard deviation. High value of mean represents an important overall influence on the output by the given parameter; whereas high values of the standard deviation for the  $j$ -th parameter means that it is involved in interaction with other

parameters, or whose effect is nonlinear.

## Conclusion

In this research paper we have presented a new approach for inferring the parameters in S-system models of gene regulatory networks. The CMA-ES algorithm has been used for this complex optimization task, and 5 different instances have been taken into account to evaluate its performances and its robustness: 2 instances with 2 genes - 12 parameters need to be inferred for each network; 1 instance with 4 genes - 40 parameters to be inferred; and 2 artificial networks with 5 genes - 60 parameters must to be inferred for each instance. The proposed algorithm has been compared with 7 state-of-the-art algorithms: (1) *Voit's* algorithm, (2) MO-HDE; (3) coop-CE; (4) HDE; (5) and (6) two different versions of trigonometric differential evolution; and (7) PEACE1. The first experiments have been done on the instances with  $n = (2, 4, 5)$  components taken from (Vilela et al., 2008a), comparing also CMA-ES with *Voit's* algorithm. Due to the limit pages only the Table with the results obtained on a genetic network with  $n = 5$  genes has been included in the paper. Analyzing the results obtained on all instances appear to be clear how CMA-ES is more able to estimating in a better way the parameters target, either in order to the success rate and in term of Euclidean distance. To have a better knowledge about the robustness of CMA-ES, we have compared it also with the current state-of-the-art algorithms, where the Euclidean distance has been used as evaluation metric. From these comparisons, CMA-ES is the only algorithm able to inferring the parameters effectively. Reviewing all experiments from an overall point of view is possible to claim that CMA-ES is an effective optimization algorithm for complex tasks, ranking as among one of the best reverse engineering methodologies on S-system models. Finally, in this research paper has been also included a study on the convergence process of CMA-ES through Time-To-Target plots, which are a way to characterize the running time of stochastic algorithms; and a global sensitivity analysis method, the Morris' algorithm.

## Abstract

Quinn (2001) sought to demonstrate that communication between simulated agents could be evolved without pre-defined communication channels. Quinn's work was exciting because it showed the potential for ALife models to look at the real origin of communication; however, the work has never been replicated. In order to test the generality of Quinn's result we use a similar task but a completely different agent architecture. We find that qualitatively similar behaviours emerge, but it is not clear whether they are genuinely communicative. We extend Quinn's work by adding perceptual noise and internal state to the agents in order to promote ritualization of the nascent signal. Results were inconclusive; philosophical implications are discussed.

## Introduction

Artificial life researchers have been modelling the evolution of communication for some time now (for early examples see MacLennan, 1992; Werner and Dyer, 1992; Noble and Cliff, 1996). Communication is of interest in our field for a range of overlapping reasons, most notably because it is associated with two of the major transitions in evolution (Maynard Smith and Szathmáry, 1995): the jump from solitary to social living; and the later development of language and culture in our own species. ALife's agent-based simulations are a natural match for this research area as they can provide emergent explanations of communication and related co-evolutionary phenomena that are not possible using more traditional modelling techniques.

However, prior to the publication of a seminal paper by Quinn (2001), computational models of the origins of communication and language were missing an important opportunity. Influenced by game theory, by the long shadow of Shannon and Weaver (1949), and by what Lakoff and Johnson (1980) called "the conduit metaphor" for communication, modellers tended to assume that a signalling channel already existed between the relevant agents, and that the thing to be explained was how and why that signalling channel would come to be used for honest, coherent, and reliable communication. MacLennan's (1992) early work, for example, imagined agents with eight possible world states, each

matched with one of eight preferred responses, and a convenient library of eight ready-made symbols that had to be mapped, over evolutionary time, in a way that would allow pairs of agents to communicate and thus perform optimally.

These kinds of models ignored the apparently vicious circle involved in the evolution of natural communication systems: for a signal to have any meaning, for it to be worth producing, there has to be a community of responders. But why would the appropriate response behaviour already exist if the signal itself has not evolved yet?

This paradox had been noted, and resolved, many years earlier by the ethologists (Tinbergen, 1964). The two key concepts in the ethological picture of the evolution of communication are "intention movements" — non-signals which provide the raw materials for signal evolution — and the subsequent "ritualization" of the nascent signal. Intention movements have not been selected for *per se*; they are simply a physically necessary step in performing some action, e.g., an animal that intends to bite an opponent *must* bare its teeth before doing so. Intention movements thus provide information about future behaviour, and it is not difficult to see how such movements, coupled with the complementary ability to recognize them, might provide the seeds for the evolution of a communication system. Ritualization is what happens when an initially irrelevant movement such as teeth-baring starts to be of informational value to other animals. The ethologists, assuming that the reliable transmission of information would always carry a selective advantage, thought that the original cue would then be exaggerated or stylized in the interests of reducing ambiguity.

Inspired in part by the ethological perspective, Quinn (2001) sought to demonstrate in a simulation that communication between agents could be evolved without pre-defined communication channels; in other words, he hoped to produce a genuine account of the *origin* of communication. Quinn's point was that by supplying a signalling channel and a library of signals, most of the previous models were assuming the existence of exactly what it was they should be trying to explain. He began with pairs of agents that were linked only by basic sensory-motor interaction, i.e., if one

agent moved this could be detected by the visual system of the other agent. The agents were then faced with an explicitly cooperative task: moving their joint centre of mass as far as possible within a time limit. A genetic algorithm (GA) was used to select for agents that, when paired with another member of the population, managed to coordinate their behaviour and score highly on the task. Quinn interpreted his results as showing that communication had evolved in the form of a dance-like negotiation process between the agents that was followed by matched movement away from their starting positions. Note that no explicit role allocation had been forced on the agents: each one was equally likely to end up as the leader or the follower in the movement phase.

Quinn's work was exciting because it showed the potential for ALife models to look at the real origin of communication, rather than just the conditions under which it could be maintained in a system where it was already possible. The model is appealing in that it provides a great example of the kind of emergent explanation that ALife can provide, and a potential bridging account between two levels of description (i.e., the level of raw sensory-motor interaction and the level of symbols and reference). It is also a valuable contribution to the biological literature on communication because it lends support to the ethological theory of intention movements and ritualization. Finally, Quinn (2001) is a very popular paper, having been cited 113 times as of April 2011, according to Google Scholar.

However, Quinn's work has never been replicated. We feel that precisely because Quinn's approach is so promising, it is important to establish its generality before going further: one goal of the current paper is to check whether Quinn's central result is robust. Quinn was working in the area of evolutionary robotics and used a fairly detailed model of a real robot; he also employed a continuous-time recurrent neural network (CTRNN) as the evolvable control architecture. What if his result was a freak occurrence, and turned out to be contingent on some detail of the robot's sensory system or cognitive architecture? The general finding should be robust across these specific details if it is going to be of any value, and therefore we have attempted to replicate Quinn's work using a different model of agent perception and movement, as well as a different evolvable control architecture.

We also want to ask: did Quinn pick the right task? He showed the emergence of (at least) a coordination protocol between pairs of agents, but did he definitively show the evolution of communication? This in turn raises questions about how to define communication and how to distinguish it from "mere" coordinated behaviour; we will address these issues below. Scheutz and Schermerhorn (2008) make the point that in many simple ALife scenarios, there may not in fact be any selective pressure for a communicative solution, and we feel this may regrettably apply in the Quinn case.

Figure 1: The layout of the ray-cast sensors of our agents. Note that this is not an exact replication of Quinn's simulated Khepera robots. The diagram is not to scale: robot diameter is 55 mm and maximum sensor range is 50 mm.

## The model

Our goal in the first instance is to find out how general Quinn's result was, and thus we have set up a similar task but used a completely different agent architecture. Quinn's agents were fairly realistic simulations of a *Khepera* — these are small, low-cost cylindrical robots, 55 mm in diameter and 30 mm in height, with two independent motors driving two wheels, and a set of eight infra-red (IR) proximity sensors giving the robot the ability to perceive nearby objects. We constructed our own 2D simulator that was less detailed than Quinn's. Our agents are of the same size and shape as a *Khepera* robot but the sensors are of a different kind, number, and position: see figure 1 for details. Most of the changes we have made to Quinn's design are arbitrary, and that is exactly the point. We need to keep certain basic features the same so that the coordinated movement task is both recognizable and feasible, but beyond that our simulation will work best as a measure of the generality of Quinn's result if it is as different as possible.

The agents have been simplified in several ways, but the cylindrical shape has been kept in order to make them rotationally invariant and thus prevent any simple short-cuts that would allow one agent to detect the orientation of its partner. The drive wheels of the *Khepera*, and details such as inertia and friction, are no longer simulated. Movement and rotation are simply transforms in the two-dimensional simulated environment; agents are moved and rotated around their centre-point. The eight IR sensors have been replaced

by ten ray-cast sensors. They operate by throwing a ray of a certain length and infinitesimal width along the vector the sensor is pointing to. If the ray collides with the other agent (there is nothing else in the environment) within its 50 mm range, the sensor reports the collision distance. If the ray gets to the end of its range without colliding with anything (either because the other agent is not present in that direction, or is more than 50 mm away) the sensor reports 51 mm. Since the amount of space covered by these sensors is significantly smaller than the overlapping fan-shaped response areas of the IR sensors, two additional sensors have been added, bringing the total to ten per agent.

Instead of using a CTRNN as a controller, as Quinn did, our model is based on a simple production-rule system. This is much like a classifier system but with the real-time learning capability removed. Every rule or classifier is composed of a set of ten sensor threshold values, logical operators linking each of these, a comparator condition describing how the sensor values should be compared with the thresholds (less than, greater than, or equal to) and an associated behaviour. Classifiers are fired when the sensory input of the agent at a given time-step matches the classifier condition. When no classifier can be matched a default behaviour is chosen. Every classifier also has a “weight” to avoid clashes when more than one classifier matches the sensory input. In such cases the highest-weighted classifier is fired. Note that the weight of a classifier is not altered by experience: it is a purely random value which can be affected by mutation as can the rest of the classifier.

Agents with internal state are introduced later on in the paper (the initial agents do not have internal state) and they are effectively finite-state machines. Classifiers are specific to a particular internal state of the agent, and when a classifier is fired the state of the agent changes to the output state of the classifier. If no classifier can be matched, there is a default output state, and thus any time the default behaviour is fired, the agent switches to this default state.

In order to make this a replication, the task the agents face is exactly the same as in Quinn’s work: a pair of agents must move their joint centre of mass as far as possible while staying within each other’s sensor range and without colliding. We used much the same type of GA as Quinn did to evolve the population of agents, but some of the parameters employed, as well as the way fitness is computed, are different. As in the original model, there is no predefined role allocation. Agents are drawn randomly from a population of 25 individuals and evaluated in pairs. The initial positions and angles of every pair are not randomly generated but picked from a predefined set (see Quinn’s original paper for more details). Each pair is given 15s (in simulation time) to solve the task. Evaluation is performed in discrete time steps of 0.25s; at every time step new sensor values are computed for both agents; and finally the agent behaves according to its sensory input through the activation of the

highest-weighted matching classifier. Each agent in the pair gets the same score depending on their joint performance. A selection process keeps the best 60% of agents and deletes the rest in every generation, with new agents being created through recombination and mutation of the successful individuals of the previous generation. Recombination is performed as an uniform macro crossover operation by combining the classifiers from both parents. Since recombination is performed at a macro scale, classifiers are never split. Every classifier element is susceptible of mutation. Mutation rates are, depending on the number of state bits, 0.21 (stateless case), 0.22 (1 bit state case) or 0.23 (2 bits state case).

The fitness of every pair of agents is computed as an average over two different terms. The first term measures whether or not the agents are in each other’s sensory range and is itself averaged across all simulation time steps. This term is important in shaping effective solutions, as the agents are effectively very short-sighted and moving out of sensor range is usually a disaster for the over-arching goal of moving the joint centre of mass in a consistent direction. The score of an agent on a given time step is computed as an exponential decay function on the distance to the other agent. If an agent is in sensor range the fitness obtained is 1.0, otherwise fitness decreases exponentially with the distance. The maximum distance is computed as the maximum linear distance an agent could achieve given its linear velocity and the overall simulation time.

At the end of the simulation the second fitness term is computed: it measures the distance that the agents have travelled. If *either* agent has travelled at least 250 mm then this component of fitness is 1.0. If the agents have travelled a shorter distance from their starting positions, this fitness component will be the quotient of the distance travelled by whichever agent has travelled the furthest, over the target distance. Note that an agent could travel approximately 500 mm — double the target distance — during the time available if it moved away in a straight line, which means that the fitness function allows the agents a reasonable amount of time for potential communication before movement begins in earnest.

Even though the overall goal is moving the joint centre of mass, we do not measure this directly. Optimal performance is achieved by staying in sensor range *and* moving as far as possible. The final fitness score is the average of the two terms described above, and thus the maximum score is 1.0. Fitness scores of 0.5 are relatively easily achieved by either not moving at all (thus staying in sensor range and scoring highly on the first component) or moving off in random directions at full speed (scoring highly on the second component).

Finally, at the end of a generation the final fitness of each agent is equal to the average of its scores across many different evaluations with different partners and in different initial positions. Note that all initial positions have the agents start-

	<i>Front</i>				<i>Right</i>				<i>Rear</i>				<i>Left</i>

Rule 1	49	∨	9	∧	35	∧	37	∧	29	∨	13	∧	33	∨	29	∧	18	∧	19	Forward
Rule 2	14	∨	16	∧	47	∧	37	∧	47	∧	20	∧	38	∨	10	∧	23	∨	26	Backward
Rule 3	23	∧	39	∨	49	∨	14	∧	40	∨	16	∨	35	∨	8	∧	27	∧	20	Rotate CCW
Rule 4	49	∨	9	∧	2	∧	37	∧	29	∧	19	∧	4	∨	37	∧	26	∨	19	Forward
Rule 5	3	∧	9	∧	15	∨	43	∧	14	∧	8	∧	6	∨	44	∧	38	∨	20	Backward
Default																				Rotate CCW

Table 1: The production rule set of a high-performing strategy found during the replication runs (this rule set leads to perfect performance on the task). For each rule, the table lists the threshold value in mm for each of the ten sensors, and the logical operator (either “and” or “or”) used to link them. In every case the rules used the “less than” comparator, i.e., the value would be true if the other agent was detected at the given distance or closer. Note the mix of “forward”, “backward”, and “rotate counter-clockwise” behaviours that combine to produce coordinated movement. An agent that could detect nothing within sensor range would fall through to the default behaviour of counter-clockwise rotation.

ing inside each other’s 50 mm sensor range.

### Replication results

We ran our simulation 30 times, with each run lasting 2000 generations.

Quantitatively our mean and maximum fitness values were similar to Quinn’s despite the differences in the agent architecture, the GA, and the fitness function. Some of the agents scored very high and even perfect fitness levels although these could not be maintained in the long run as mutation pressure prevented the population as a whole from adopting an optimal strategy. Table 1 shows one of the best rule sets evolved.

Qualitatively, we have analyzed in detail the kinds of strategies that evolved in the most successful runs. Although many different strategies evolved that could accomplish the coordination task, we found that the most common and the most successful one we observed fits reasonably well with the main strategy described by Quinn. Figure 2 illustrates the sequence of behaviours. Both agents start rotating counter-clockwise (A) until the first agent (shown in brown) reaches its favoured alignment relative to the second agent (shown in white) and starts moving one step forward and one step backwards in order to “signal” its readiness and direction to the second agent (B). In the meantime, the second agent keeps rotating counter-clockwise until it matches the first agent’s alignment (C). When both agents are aligned and pointing in opposite directions, the first agent starts moving backwards while the second agent starts moving forward, and thus they move together until the end of the time frame (D). Many variations on this strategy exist, with varying degrees of speed and reliability in achieving alignment. Quinn also notes that the strategy he picked to illustrate the behaviour of the agents is just one of the simplest cases among many variants observed.

The change in the number of collisions over evolutionary time also matches Quinn’s results. The collision rate is ex-

tremely high in the early generations but rapidly decreases as fitness increases. Sudden decreases in the collision rate usually match fitness jumps even though our implementation does not include an explicit penalty for collisions. We can also confirm that, as Quinn stated, the evolution of successful behaviours is extremely sensitive to the initial conditions used (the starting distance between the two agents and their relative orientations) as well as to how the agents are evaluated. In essence every agent has to be evaluated with every possible angle and distance: random runs in which every agent is evaluated with different randomly chosen starting distances and relative orientation angles are completely unsuccessful.

There were many differences introduced between Quinn’s setup and our own, notably the use of a different sensory system and control architecture. Nevertheless we managed to replicate Quinn’s findings: very similar behaviours evolved. We therefore suggest that the emergence of coordinated (and possibly communicative) behaviour to solve this type of task is likely to be a general and framework-independent finding.

### Re-examination of the Quinn paradigm

In the previous section we reported the successful replication of a dance-like negotiation phase between the pairs of agents. This is a pleasing result as it goes some way towards showing that Quinn’s findings are general. However, we did not observe any unequivocal “ritualization” process by which the signal became more exaggerated over time. This led us to wonder whether our agents were really communicating at all.

So what do we mean by communication anyway? Should we expect a sharp dividing line between coordinated behaviour and “true” communication? Some ideas from the philosopher Millikan (1984) will be useful here. She argues that although there is no *sharp* line between those two categories, there is certainly a distinction worth making. Millikan lays out four classes of representational phenomena,

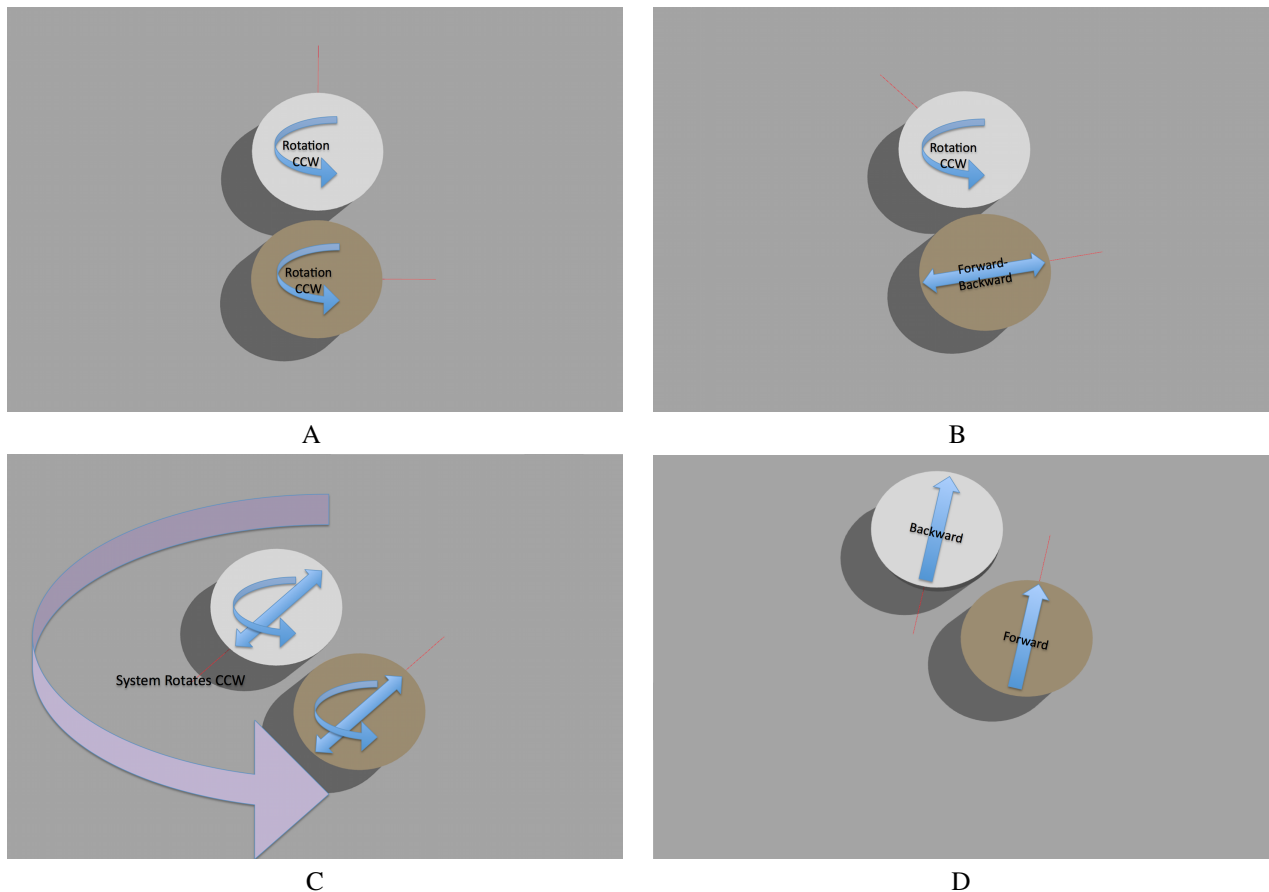

Figure 2: Illustration of the evolved sequence of behaviours in a typical case. A: agents rotate until one reaches a favoured orientation. B: the first agent to achieve this starts moving backwards and forwards. C: the second agent orbits the first until it is aligned in the opposite direction. D: the two agents move away together, with the second agent moving in reverse.

in order of increasing sophistication: tacit suppositions, intentional icons, inner representations, and mental sentences. The first two are all we will need given the simplicity of our agents. (Millikan's typology was initially directed at the issue of what might count as an internal representation within a single organism but it is relevant to our purposes as she sees communication as simply the exchange of representations between organisms.)

Tacit suppositions occur when the design of an organism meshes so neatly with a feature of the environment that it is tempting to say the design "represents" that feature. For example, if a biological clock produces a cycle close to 24 hours then we may be tempted to say that the clock mechanism somehow represents the length of the day. Millikan refers to such adaptations as tacit suppositions because they presuppose certain facts about the environment in order that their evolved function is fulfilled.

For a system to qualify as minimally representational, it must involve more than tacit suppositions. Firstly, there must be something identifiable as the representation itself: an "icon". Furthermore, the icon must have a "producer"

and a "consumer". It must be the function of the producer to generate the icon in accordance with a mapping rule that relates one or more dimensions of possible variance in the icon to variance in the environment. It must be the evolved function of the consumer to use or be guided by the icon in some way. If all of these conditions are met, Millikan suggests that the system involves an "intentional icon". For example, the waggle dance of the honeybee is a paradigm case of an intentional icon: the dance itself is the icon, the dancing bee is the producer, and a mapping rule relates the angle and duration of the dance to the direction and distance to a food source. The watching bees are the consumers of the icon, because it is the adaptive function of the dance to guide them to the food source. The important point is that there is a difference between tacitly supposing that the world — including your interaction partners — regularly works in a certain way, and evolving a distinct behaviour or trait that has been selected for on both sides (production and reception) precisely because it conveys information from one agent to the other.

Consider the difference between two scenarios. In the first

one, you are at home, and it is my job to pick you up in a car. I drive to your house: you are not outside, so I drive around the block repeatedly and check again for your presence each time I go by. Assuming I do that reasonably reliably, you can tacitly suppose the existence of my strategy, and go out into the street whenever you see my car going by. I will then see you and stop to pick you up on the next cycle. Both of us have strategies that rely on the other one acting a certain way but neither strategy has been exaggerated into a signal. We are coordinated but not communicative. The second scenario is exactly the same, except that through some adaptive process we have arrived at a communicative solution: I honk the horn three times in quick succession, and you come outside in response.

These two scenarios demonstrate the difficulty of showing that Quinn's (or our) observed behaviours are anything more than coordinated. Each agent is tacitly supposing that the other will rotate, align, move forwards and/or backwards, etc. The dance-like movement is, on the surface, reminiscent of the bee dance, and we suspect this resemblance has made many readers of Quinn's original paper confidently interpret the behaviour as communication. However, it is important to note that there is no mapping rule and no clear referential signalling going on.

What would it take to make Quinn's negotiation dance a signal? In answering this question, Millikan would agree closely with the ethologists. Non-signalling behaviours must provide the seed for signalling behaviours — how could it be otherwise? So the thing to look for in classifying something as "real communication" is a history of selection for exaggeration on both sides, both in the production of the signal and the sensitivity or scale of the response. In Quinn's paradigm we do not really see this: as far as we can tell from historical analyses of our runs, the agents hit on their coordination strategy and it remains essentially unchanged.

Quinn's dance in its current form appears to be a borderline case: it surely qualifies as an intention movement, and is quite possibly ripe for exaggeration into a signal. In the next section we try to push things towards communication by adding both perceptual noise and internal state to the agents. Noise may make a difference in that we can imagine the "dance signal" being exaggerated or strengthened to make sure it cannot be misunderstood in a noisy environment. State is a slightly different story: our stateless agents are necessarily reactive. It is not clear whether Quinn's CTRNN agents had any internal state; they might have, due to the possibility of recurrent connections. If we add state bits and find that this improves performance, that means that the task was "state-hungry", which in turn suggests a potential interpretation in terms of intentional icons, i.e., that the agents could be communicating about their current internal state.

## Results of the extended model

We extended our replication of Quinn's model to try to assess whether or not the evolved behaviours really qualify as communicative. In order to do so we have added two new features: perceptual noise and internal state. The addition of Gaussian noise to the sensory inputs adds ambiguity to the perceptual world of the agents and would seem likely to make the task more difficult. Thus it might be a driver for more explicitly communicative strategies. The second extension is the addition of 1 and then 2 bits of internal state to the agents. The acquisition of internal state enhances the cognitive capabilities of the agents, giving them more behavioural options than a purely reactive agent. This should make it easier for the agents to sequence their coordinated behaviours over time, but for our purposes it may also give them something to communicate *about*, i.e., their current internal state values.

We added 17 new sets of 30 runs each, employing different noise values (0%, 1%, 2%, 4%, 8% and 16%) and adding either 0, 1 or 2 bits of internal state to the agents. In the end we have a total of 18 run sets (including the original noiseless-stateless run) exploring every combination of noise and number of state bits. In order to reflect the increased range of behavioural possibilities that come with having internal state, we have also increased the number of classifiers from 5 (in stateless runs) to 10 (for 1-bit state runs) and 15 (for 2-bit state runs).

The results are presented in figure 3; the general pattern is in line with our expectations. We can see that the addition of noise decreases the performance of the agents in solving the task. On the other hand, the addition of state seems to make the task easier: the 2-bit condition is only slightly superior to the 1-bit condition, but both increases the mean fitness of the population over the stateless case.

When looking at the different runs individually, we find that state-equipped agents evolved more robust strategies than stateless ones. In fact, some of the 2-bit state solutions reach consistently optimal performance across the lower noise levels. In such cases, the mean fitness of the population reaches a sustained score of 1.0 with only occasional perturbations due to the randomness added by mutation. Since we have not observed such robust performance in any of the of the stateless runs we take this as evidence that the task chosen by Quinn, despite its simplicity, is "state-hungry".

In order to qualitatively assess whether or not the agents were evolving genuinely communicative solutions, we looked for the equivalent of Tinbergen's "intention movements" in the early stages of each evolutionary time line, and looked also for their ritualization or exaggeration into proper signals. We have found *some* suggestive cases of exaggeration in state-equipped runs, in particular for the forward-backwards movement that Quinn originally highlighted as a suspected signal. The movement sometimes becomes ex-

Figure 3: Results from the extended model. Mean fitness reached at the end of the evolutionary run is shown for various combinations of perceptual noise level and the number of state bits. Each plotted data point is an average across 30 replications. Standard errors across these replications are not shown for reasons of clarity, but the mean size of the standard error was 0.013. The general result is that performance is reduced as noise levels increase, and that at least one bit of state leads to better performance on the task.

aggregated just before the population starts to score perfect fitness scores. The exaggeration consists of a two-steps-forward-two-steps-backwards routine instead of the former one-step-forward-one-step-backwards. Despite this interesting result, we found no indications of a general trend. Furthermore, the runs that evolved such exaggerated “signals” were not among the runs with the highest overall average fitness (although, on the other hand, this kind of exaggeration never appeared in stateless runs). It may be that the task picked by Quinn is not “communication hungry”, i.e., it does not require explicit information transmission between the agents in order to achieve optimal performance levels (see Scheutz and Schermerhorn, 2008).

## Conclusions

We have achieved one of our goals, in demonstrating the generality of Quinn’s (2001) finding that sensory-motor interaction with no pre-defined communication channels can lead to coordinated behaviour. The result does not seem to be dependent on specific details of Quinn’s setup such as the CTRNN control architecture.

We also asked some critical questions as to whether the dance-like coordination behaviour should be seen as communicative. We extended Quinn’s model to include in-

creased levels of perceptual noise, and internal state for the agents. This was done with the intention of pushing the agents into developing exaggerated signalling and response behaviours over evolutionary time that would more clearly fit the definition of communication. Unsurprisingly, we found that higher levels of noise make the task more difficult. We also found that adding one or two bits of internal state improved performance, indicating that Quinn’s task is somewhat “state hungry”. Unfortunately we were not able to get consistent evidence of signal exaggeration and ritualization. We have to conclude that the dance-like coordination behaviour exhibited by the agents is at best a borderline case of true signalling.

The difficulty is that Quinn’s chosen task simply appears not to provide selective pressure for communication in Milikan’s sense of producing intentional icons. Scheutz and Schermerhorn (2008) have noted that this is true of many of the simple scenarios employed by ALife researchers. If we look at the world inhabited by our agents, it becomes clear that there is effectively not much to talk about: they always begin their interaction within sensor range of each other, the other agent is the only feature in the world and thus the only thing that can be detected by their sensors, and the cooperative goal of joint movement is always consistent. Once a co-

ordinated solution has been evolved, the agents are already performing near-optimally and there is no evolutionary pressure towards any exaggeration of the signal. We suspect that a promising direction for future work in this area is to use tasks in which referential communication about distant objects is essential for optimal performance (see e.g., Williams et al., 2008).

Why does all this matter anyway? Coordination or communication — what’s the difference? We believe it matters because there are two very different messages one can take from Quinn’s original finding. On the one hand you may see Quinn’s result as showing how the *appearance* of communication can be explained away as being just the result of mechanical feedback loops in a physical system. Some “enactivist” thinkers in ALife appear to endorse this position. The hope is to eventually demonstrate that human-level intelligence is really made up of a toolkit of sensory-motor tricks and hacks; Beer’s (2003) dynamical systems approach is a good example.

On the other hand, Quinn’s result can be seen as an attempt to bridge two levels of description. Quinn published his paper out of frustration with previous ALife work on signalling that constantly presupposed the very thing it was trying to explain, but that does not mean that he hoped to render talk of signals and channels irrelevant. If a model like Quinn’s could successfully show that communication can indeed emerge from sensory-motor interactions, we could take that not as undermining the concept of communication but as explaining how one level of description (L2: that of signals, symbols, and representations) can emerge from another (L1: the mechanics of sensory-motor feedback).

It has been argued (de Pinedo and Noble, 2008) that in explaining the behaviour of evolved agents, both agent- and sub-agent-level explanations will be necessary — and models like Quinn’s seem a useful step in that direction. Having established that L1 can give rise to L2, we thus establish that every subsequent simulation which incorporates L2-type communication does not need to provide direct evidence of the origins of that communication — we are safe in assuming that said communication would evolve in some fashion or other. Models like Quinn’s can thus provide *bridging explanations*: they verify the relationship between L1 and L2 and then allow those interested in L2 alone to get on with simulating phenomena at that level, confident that L2’s origins are understood.

The question as to which of these two views of communication and reference will ultimately prevail is of course still open. However, we are convinced that ALife simulations such as Quinn’s provide a uniquely valuable testing ground for working out the consequences of either approach.

# Detecting emergent processes in cellular automata with excess information

## Abstract

Many natural processes occur over characteristic spatial and temporal scales. This paper presents tools for (i) flexibly and scalably coarse-graining cellular automata and (ii) identifying which coarse-grainings express an automaton's dynamics well, and which express its dynamics badly. We apply the tools to investigate a range of examples in Conway's Game of Life and Hopfield networks and demonstrate that they capture some basic intuitions about emergent processes. Finally, we formalize the notion that a process is emergent if it is better expressed at a coarser granularity.

## Introduction

Biological systems are studied across a range of spatiotemporal scales – for example as collections of atoms, molecules, cells, and organisms (Anderson, 1972). However, not all scales express a system's dynamics equally well. This paper proposes a principled method for identifying which spatiotemporal scale best expresses a cellular automaton's dynamics. We focus on Conway's Game of Life and Hopfield networks as test cases where collective behavior arises from simple local rules.

Conway's Game of Life is a well-studied artificial system with interesting behavior at multiple scales (Berlekamp et al., 1982). It is a 2-dimensional grid whose cells are updated according to deterministic rules. Remarkably, a sufficiently large grid can implement any deterministic computation. Designing patterns that perform sophisticated computations requires working with distributed structures such as gliders and glider guns rather than individual cells (Dennett, 1991). This suggests grid computations may be better expressed at coarser spatiotemporal scales.

The first contribution of this paper is a coarse-graining procedure for expressing a cellular automaton's dynamics at different scales. We begin by considering cellular automata as collections of spacetime coordinates termed occasions (cell  $n_i$  at time  $t$ ). Coarse-graining groups occasions into structures called *units*. For example a unit could be a  $3 \times 3$  patch of grid containing a glider at time  $t$ . Units do not have to be adjacent to one another; they interact through

*channel* – transparent occasions whose outputs are marginalized over. Finally, some occasions are set as *ground*, which fixes the initial condition of the coarse-grained system.

Gliders propagate at  $1/4$  diagonal squares per tic – the grid's "speed of light". Units more than  $4n$  cells apart cannot interact within  $n$  tics, imposing constraints on which coarse-grainings can express glider dynamics. It is also intuitively clear that units should group occasions concentrated in space and time rather than scattered occasions that have nothing to do with each other. In fact, it turns out that most coarse-grainings express a cellular automaton's dynamics badly.

The second contribution of this paper is a method for distinguishing good coarse-grainings from bad based on the following principle:

- *Coarse-grainings that generate more information, relative to their sub-grainings, better express an automaton's dynamics than those generating less.*

We introduce two measures to quantify the information generated by coarse-grained systems. Effective information,  $ei$ , quantifies how selectively a system's output depends on its input. Effective information is high if few inputs cause the output, and low if many do. Excess information,  $\xi$ , measures the difference between the information generated by a system and its subsystems.

With these tools in hand we investigate coarse-grainings of Game of Life grids and Hopfield networks and show that grainings with high  $ei$  and  $\xi$  capture our basic intuitions regarding emergent processes. For example, excess information distinguishes boring (redundant) from interesting (synergistic) information-processing, exemplified by blank patches of grid and gliders respectively.

Finally, the penultimate section converts our experience with examples in the Game of Life and Hopfield networks into a provisional formalization of the principle above. Roughly, we define a process as *emergent* if it is better expressed at a coarser scale.

The principle states that emergent processes are more than the sum of their parts – in agreement with many other approaches to quantifying emergence (Crutchfield, 1994;

Tononi, 2004; Polani, 2006; Shalizi and Moore, 2006; Seth, 2010). Two points distinguishing our approach from prior work are worth emphasizing. First, coarse-graining is *scalable*: coarse-graining a cellular automaton yields another cellular automaton. Prior works identify macro-variables such as temperature (Shalizi and Moore, 2006) or centre-of-mass (Seth, 2010) but do not show how to describe a system's dynamics purely in terms of these macro-variables. By contrast, an emergent coarse-graining is itself a cellular automaton, whose dynamics are computed via the mechanisms of its units and their connectivity (see below).

Second, our starting point is selectivity rather than predictability. Assessing predictability necessitates building a model and deciding what to predict. Although emergent variables may be robust against model changes (Seth, 2010), it is unsatisfying for emergence to depend on properties of *both* the process *and* the model. By contrast, effective and excess information depend only on the process: the mechanisms, their connectivity, and their output. A process is then emergent if its internal dependencies are best expressed at coarse granularities.

### Probabilistic cellular automata

**Concrete examples.** This paper considers two main examples of cellular automata: Conway's Game of Life and Hopfield networks (Hopfield, 1982).

The Game of Life is a grid of deterministic binary cells. A cell outputs 1 at time  $t$  iff: (i) three of its neighbors outputted 1s at  $t - 1$  or (ii) it and two neighbors outputted 1s at  $t - 1$ .

In a Hopfield network (Amit, 1989), cell  $n_k$  fires with probability proportional to

$$p(n_{k,t} = 1 | n_{\bullet,t-1}) \propto \exp \left[ \frac{1}{T} \sum_{j \rightarrow k} \alpha_{jk} \cdot n_{j,t-1} \right] \quad (1)$$

Temperature  $T$  controls network stochasticity. Attractors  $\{\xi^1, \dots, \xi^N\}$  are embedded into a network by setting the connectivity matrix as  $\alpha_{jk} = \sum_{\mu=1}^N (2\xi_j^\mu - 1)(2\xi_k^\mu - 1)$ .

**Abstract definition.** A *cellular automaton* is a finite directed graph  $X$  with vertices  $V_X = \{v_1 \dots v_n\}$ . Vertices are referred to as occasions; they correspond to *spacetime* coordinates in concrete examples. Each occasion  $v_l \in V_X$  is equipped with finite output alphabet  $A_l$  and Markov matrix (or *mechanism*)  $p_l(a_l | s_l)$ , where  $s_l \in S_l = \prod_{k \rightarrow l} A_k$ , the combined alphabet of the occasions targeting  $v_l$ . The mechanism specifies the probability that occasion  $v_l$  chooses output  $a_l$  given input  $s_l$ . The input alphabet of the entire automaton  $X$  is the product of the alphabets of its occasions  $X_{in} := \prod_{l \in V_X} A_l$ . The output alphabet is  $X_{out} = X_{in}$ .

*Remark.* The input  $X_{in}$  and output  $X_{out}$  alphabets are distinct copies of the same set. Inputs are causal interventions imposed via Pearl's  $do(-)$  calculus (Pearl, 2000). The probability of output  $a_l$  is computed via the Markov matrix:

$p_l(a_l | do(s_l))$ . The  $do(-)$  is not included in the notation explicitly to save space. However, it is always implicit when applying any Markov matrix.

A Hopfield network over time interval  $[\alpha, \beta]$  is an abstract automaton. Occasions are spacetime coordinates – e.g.  $v_l = n_{i,t}$ , cell  $i$  at time  $t$ . An edge connects  $v_k \rightarrow v_l$  if there is a connection from  $v_k$ 's cell to  $v_l$ 's and the time coordinates are  $t - 1$  and  $t$  respectively for some  $t$ . The mechanism is given by Eq. (1). Occasions at  $t = \alpha$ , with no incoming edges, can be set as fixed initial conditions or noise sources. Similar considerations apply to the Game of Life.

Non-Markovian automata (whose outputs depend on inputs over multiple time steps) have edges connecting occasions separated by more than one time step.

### Coarse-graining

Define a *subsystem*  $X$  of cellular automaton  $Y$  as a subgraph containing a subset of  $Y$ 's vertices and a subset of the edges targeting those vertices. We show how to coarse-grain  $X$ .

**Definition** (coarse-graining). *Let  $X$  be a subsystem of  $Y$ . The coarse-graining algorithm detailed below takes  $X \subset Y$  and data  $\mathcal{K}$  as arguments, and produces new cellular automaton  $X_{\mathcal{K}}$ . Data  $\mathcal{K}$  consists of (i) a partition of  $X$ 's occasions  $V_X = \mathbf{G} \cup \mathbf{C} \cup \mathbf{U}_1 \cup \dots \cup \mathbf{U}_N$  into ground  $\mathbf{G}$ , channel  $\mathbf{C}$  and units  $\mathbf{U}_1 \dots \mathbf{U}_N$  and (ii) ground output  $s^{\mathbf{G}}$ .*

Vertices of automaton  $X_{\mathcal{K}}$ , the new coarse-grained occasions, are units:  $V_{X_{\mathcal{K}}} := \{\mathbf{U}_1 \dots \mathbf{U}_N\}$ . The directed graph of  $X_{\mathcal{K}}$  is computed in Step 4 and the alphabets  $\mathbf{A}_l$  of units  $\mathbf{U}_l$  are computed in Step 5. Computing the Markov matrices (mechanisms) of the units takes all five steps.

The ground specifies occasions whose outputs are fixed: the initial condition  $s^{\mathbf{G}}$ . The channel specifies unobserved occasions: interactions between units propagate across the channel. Units are macroscopic occasions whose interactions are expressed by the coarse-grained automaton. Fig. 1 illustrates coarse-graining a simple automaton.

There are no restrictions on partitions. For example, although the ground is intended to provide the system's initial condition, it can contain any spacetime coordinates so that in pathological cases it may obstruct interactions between units. Distinguishing good coarse-grainings from bad is postponed to later sections.

**Algorithm.** Apply the following steps to coarse-grain:

**Step 1.** *Marginalize over extrinsic inputs.*

External inputs are treated as independent noise sources; we are only interested in *internal* information-processing. An occasion's input alphabet decomposes into a product  $S_l = S_l^X \times S_l^{Y \setminus X}$  of inputs from within and without the system. For each occasion  $v_l \in V_X$ , marginalize over external outputs using the uniform distribution:

$$p_l(a_l | s_l^X) := \sum_{S_l^{Y \setminus X}} p_l(a_l | s_l^X, s_l^{Y \setminus X}) \cdot p_{unif}(s_l^{Y \setminus X}). \quad (2)$$

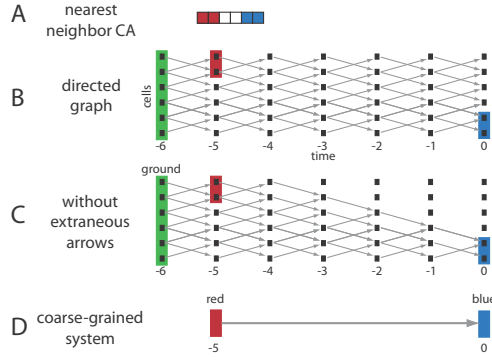

Figure 1: (A) An automaton of 6 cells connected to their immediate neighbors. (B): The directed graph of occasions over time interval  $[-6, 0]$ . Green occasions are ground. Red and blue occasions form two units. Other occasions are channel. (C): Edges whose signals do not reach the blue unit have no effect. (D): The coarse-grained system consists of two units (macro-occasions).

### Step 2. Fix the ground.

Ground outputs are fixed in the coarse-grained system. Graining  $\mathcal{K}$  imposes a second decomposition onto  $v_l$ 's input alphabet,  $S_l^X = S_l^G \times S_l^C \times S_l^U$  where  $U = \cup_k U_k$ . Subsume the ground into  $v_l$ 's mechanism by specifying

$$p_l^G(a_l | s_l^C, s_l^U) := p_l(a_l | s_l^G, s_l^C, s_l^U).$$

### Step 3. Marginalize over the channel.

The channel specifies transparent occasions. Perturbations introduced into units propagate through the channel until they reach other units where they are observed. Transparency is imposed by marginalizing over the channel occasions in the product mechanism

$$p_{\mathcal{K}}(x_{out}^{\mathcal{K}} | x_{in}^{\mathcal{K}}) := \sum_{l \in \mathbf{C}} \prod_{l \in \mathbf{C} \cup \mathbf{U}} p_l^G(x_{out}^l | x_{in}^l), \quad (3)$$

where superscripts denote that inputs and outputs are restricted, for  $\mathcal{K}$ , to occasions in units in  $\mathcal{K}$  (since channel is summed over and ground is already fixed) and, for each  $l$ , to the inputs and outputs of occasion  $v_l$ .

For example, consider cellular automaton with graph  $v_a \rightarrow v_b \rightarrow v_c$  and product mechanism  $p(c|b)p(b|a)p(a)$ . Setting  $v_b$  as channel and marginalizing yields coarse-grained mechanism  $\sum_b p(c|b)p(b|a)p(a) = p(c|a)p(a)$ . The channel is rendered transparent and new mechanism  $p(c|a)$  convolves  $p(c|b)$  and  $p(b|a)$ .

### Step 4. Compute the effective graph of coarse-graining $X_{\mathcal{K}}$ .

The micro-alphabet of unit  $U_l$  is  $\tilde{\mathbf{A}}_l := \prod_{k \in U_l} A_k$ . The mechanism of  $U_l$  is computed as in Eq. (3) with the product restricted to occasions  $j \in \mathbf{C} \cup U_l$ , thus obtaining  $p_{U_l}(a_l | x_{in})$  where  $a_l \in \tilde{\mathbf{A}}_l$ .

Two units  $U_k$  and  $U_l$  are connected by an edge if the outputs of  $U_k$  make a difference to the behavior of  $U_l$ . More

precisely, we draw an edge if  $\exists a_k, a'_k \in \tilde{\mathbf{A}}_k$  such that

$$p_{U_l}(a_l | \overline{x_{in}}, a_k) \neq p_{U_l}(a_l | \overline{x_{in}}, a'_k) \text{ for some } a_l \in \tilde{\mathbf{A}}_l.$$

Here,  $\overline{x_{in}}$  denotes the input from all units other than  $U_k$ .

The effective graph need not be acyclic. Intervening via the  $do(-)$  calculus allows us to work with cycles.

### Step 5. Compute macro-alphabets of units in $X_{\mathcal{K}}$ .

Coarse-graining can eliminate low-level details. Outputs that are distinguishable at the base level may not be after coarse-graining. This can occur in two ways. Outputs  $b$  and  $b'$  have indistinguishable effects if  $p(a|b, c) = p(a|b', c)$  for all  $a$  and  $c$ . Alternatively, two outputs react indistinguishably if  $p(b|c) = p(b'|c)$  for all  $c$ .

More precisely, two outputs  $u_l$  and  $u'_l$  of unit  $U_l$  are equivalent, denoted  $u_l \sim_{\mathcal{K}} u'_l$ , iff

$$p_{\mathcal{K}}(x_{out} | \overline{x_{in}}, u_l) = p_{\mathcal{K}}(x_{out} | \overline{x_{in}}, u'_l) \text{ and} \\ p_{U_l}(u_l | x_{in}^{\mathcal{K}}) = p_{U_l}(u'_l | x_{in}^{\mathcal{K}}) \text{ for all } x_{out}, x_{in}.$$

Picking a single element from each equivalence class obtains the macro-alphabet  $\mathbf{A}_l$  of the unit  $U_l$ . The mechanism of  $U_l$  is  $p_{U_l}$ , Step 4, restricted to macro-alphabets.

## Information

This section extends prior work to quantify the information generated by a cellular automaton, both as a whole and relative to its subsystems (Balduzzi and Tononi, 2008, 2009).

Given subsystem  $m$  of  $X$ , let  $p_m(x_{out} | x_{in})$ , or  $m$  for short, denote its *mechanism* or Markov matrix. The mechanism is computed by taking the Markov matrix of each occasion in  $X$ , marginalizing over extrinsic inputs (edges not in  $X$ ) as in Eq. (2), and taking the product. It is notationally convenient to write  $p_m$  as though its inputs and outputs are  $x_{out}$  and  $x_{in}$ , even though  $m$  does not in general contain all occasions in  $X$  and therefore treats some inputs and outputs as extrinsic, unexplainable noise. We switch freely between terms “subsystem” and “submechanism” below.

**Effective information** quantifies how selectively a mechanism discriminates between inputs when assigning them to an output. Alternatively, it measures how sharp the functional dependencies leading to an output are.

The *actual repertoire*  $\hat{p}_m(X_{in} | x_{out})$  is the set of inputs that cause (lead to) mechanism  $m$  choosing output  $x_{out}$ , weighted by likelihood according to Bayes' rule

$$\hat{p}_m(x_{in} | x_{out}) := \frac{p_m(x_{out} | do(x_{in}))}{p(x_{out})} \cdot p_{unif}(x_{in}). \quad (4)$$

The  $do(-)$  notation and hat  $\hat{p}$  remind that we first *intervene* to impose  $x_{in}$  and then apply Markov matrix  $p_m$ .

For deterministic mechanisms, i.e. functions  $f : X_{in} \rightarrow X_{out}$ , the actual repertoire assigns  $\hat{p} = \frac{1}{|f^{-1}(x_{out})|}$  to elements of the pre-image and  $\hat{p} = 0$  to other elements of  $X_{in}$ .

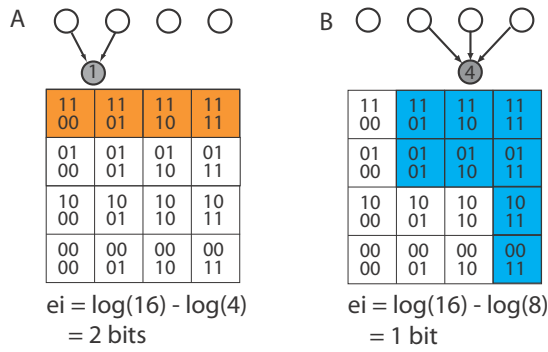

Figure 2: Categorization and information. Cells fire if they receive two or more spikes. The  $16 = 2^4$  possible outputs by the top layer are arranged in a grid. (AB): Cells  $n_1$  and  $n_4$  fire when the output is in the orange and blue regions respectively. Cell  $n_1$ 's response is more informative than  $n_4$ 's since it fires for fewer inputs.

The shaded regions in Fig. 2 show outputs of the top layer that cause the bottom cell to fire.

Effective information generated when  $m$  outputs  $x_{out}$  is Kullback-Leibler divergence ( $KL[p||q] = \sum_i p_i \log_2 \frac{p_i}{q_i}$ ),

$$ei(m, x_{out}) := KL[\hat{p}_m(X_{in}|x_{out}) || p_{unif}(X_{in})]. \quad (5)$$

Effective information is *not* a statistical measure: it depends on the mechanism and a *particular* output  $x_{out}$ .

Effective information generated by deterministic function  $f$  is  $ei(f, x_{out}) = \log_2 \frac{|X_{in}|}{|f^{-1}(x_{out})|}$  where  $|\cdot|$  denotes cardinality. In Fig. 2,  $ei$  is the logarithm of the ratio of the total number of squares to the number of shaded squares.

**Excess information** quantifies how much more information a mechanism generates than the sum of its submechanisms – how synergistic the internal dependencies are.

Given subsystem with mechanism  $m$ , partition  $\mathcal{P} = \{M^1 \dots M^m\}$  of the occasions in  $src(m)$ , and output  $x_{out}$ , define excess information as follows. Let  $m^j := m \cap (M^j \times X)$  be the restriction of  $m$  to sources in  $M^j$ . *Excess information over  $\mathcal{P}$  is*

$$\xi(m, \mathcal{P}, x_{out}) := ei(m, x_{out}) - \sum_j ei(m^j, x_{out}). \quad (6)$$

Excess information (sans partition) is computed over the information-theoretic weakest link  $\mathcal{P}^{MIP}$

$$\xi(m, x_{out}) := \xi(m, \mathcal{P}^{MIP}, x_{out}). \quad (7)$$

Let  $A_{M^j} := \prod_{l \in M^j} A_l$ . The minimum information partition<sup>1</sup>  $\mathcal{P}^{MIP}$  minimizes normalized excess information:

$$\mathcal{P}^{MIP} := \arg \min_{\mathcal{P}} \frac{\xi(m, \mathcal{P}, x_{out})}{\mathcal{N}_{\mathcal{P}}}, \text{ where}$$

$$\mathcal{N}_{\mathcal{P}} := (m-1) \cdot \min_j \{\log_2 |A_{M^j}|\}.$$

<sup>1</sup>We restrict to bipartitions to reduce the computational burden.

Excess information is negative if any decomposition of the system generates more information than the whole.

Fig. 3 shows how two cells taken together can generate the same, less, or more information than their sum taken individually depending on how their categorizations overlap. Note the figure decomposes the mechanism of the system over *targets* rather than sources and so does not depict excess information – which is more useful but harder to illustrate.

Effective information and excess information can be computed for any submechanism of any coarse-graining of any cellular automaton.

Figure 3: Independent, redundant and synergistic information. (AB): Independent. Orthogonal categorizations, orange+pink and blue+pink shadings respectively, by  $n_1$  and  $n_2$ . (C): Partially redundant. Both cells fire; categorizations overlap (pink) more “than expected” and  $ei(n_3 n_4, 11) < ei(n_3, 1) + ei(n_4, 1)$ . (D): Synergistic. Overlap is less “than expected”;  $ei(n_3 n_4, 01) > ei(n_3, 0) + ei(n_4, 1)$ .

## Application: Conway’s Game of Life

The Game of Life has interesting dynamics at a range of spatiotemporal scales. At the atomic level, each coordinate (cell  $i$  at time  $t$ ) is an occasion and information processing is extremely local. At coarser granularities, information can propagate through channels, so that units generate information at a distance. Gliders, for example, are distributed objects that can interact over large distances in space and time, Fig. 4A, and provide an important example of an emergent process (Dennett, 1991; Beer, 2004).

This section shows how effective and excess information quantifiably distinguish coarse-grainings expressing glider

Figure 4: Detecting focal points. (A): A glider moves 1 diagonal square every 4 time steps. (B): Cells in the orange and black outlined  $3 \times 3$  squares are units at  $t = 0$  and  $t = -20$  respectively, with  $x_{out}$  the glider shown. Cells at  $t = -21$  are blank ground; other occasions are channel. Shifting the position of the black square produces a family of coarse-grainings. Effective information is shown as the black square's center varies over the grid.

dynamics well from those expressing it badly.

**Effective information detects focal points.** Fig. 4A shows a glider trajectory, which passes through 1 diagonal step over 4 tics. Fig. 4B investigates how glider trajectories are captured by coarse-grainings: if there is a glider in the  $3 \times 3$  orange square at time 0, Fig. 4B, it must have passed through the black square at  $t = -20$  to get there. Are coarse-grainings that respect glider trajectories quantifiably better than those that do not?

Fig. 4B fixes occasions in the black square at  $t = -20$  and the orange square at  $t = 0$  as units (18 total), the ground as blank grid at  $t = -21$  and everything else as channel. Varying the spatial location of the black square over the grid, we obtain a *family* of coarse-grainings. Effective information for each graining in the family is shown in the figure. There is a clear focal point exactly where the black square intersects the spatiotemporal trajectory of the glider where *ei* is maximized (dark red). Effective information is zero for locations that are too far or too close at  $t = -20$  to effect the output of the orange square at  $t = 0$ .

Effective information thus provides a tool analogous to a camera focus: grainings closer to the focal point express glider dynamics better.

**Macroscopic texture varies with distance.** The behavior of individual cells within a glider trajectory is far more complicated than the glider itself, which transitions through 4 phases as it traverses its diagonal trajectory, Fig. 4A. Does coarse-graining quantifiably simplify dynamics?

Figure 5: Macro-alphabets as a function of distance. (A): Consider two families of coarse-grainings with channel and ground as in Fig. 4. First, take the blue squares (filled and empty) as units at times  $-4n$  and 0 where  $n$  is the diagonal distance between them. Second, repeat for the red squares. (B): Log-plot of the size of the filled squares' macro-alphabets as a function of  $-4n$ .

Fig. 5 constructs pairs of  $3 \times 3$  units out of occasions at various distances from one another and computes their macro-alphabets. A  $3 \times 3$  unit has a micro-alphabet of  $2^9 = 512$  outputs. The macro-alphabet is found by grouping micro-outputs together into equivalence classes if their effect is the same after propagating through the channel. We find that the size of the macro-alphabet decreases exponentially as the distance between units increases, stabilizing at 5 macro-outputs: the 4 glider phases in Fig. 4A and a large equivalence class of outputs that do not propagate to the target unit and are equivalent to a blank patch of grid. A similar phenomenon occurs for pairs of  $4 \times 4$  units, also Fig. 5.

Continuing the camera analogy: at close range the texture of units is visible. As the distance increases, the channel absorbs more of the detail. The computational texture of the system is simpler at coarser-grains yielding a more symbolic description where glider dynamics are described via 4 basic phases produced by a single macroscopic unit rather than  $2^9$  outputs produced by 9 microscopic occasions.

**Excess information detects spatial organization.** So far we have only considered grainings of the Game of Life that respect its spatial organization – in effect, taking the spatial structure for granted. *A priori*, there is nothing stopping us from grouping the 8 gray cells in Fig. 6A into a single unit that *does not* respect the spatial organization, since its constituents are separated in space. Are coarse-grainings that respect the grid-structure quantifiably better than others?

Fig. 6A shows a coarse-graining that does *not* respect the grid. It constructs two units, one from *both* gray squares at  $t = 1$  and the other from *both* red squares at  $t = 0$ . Intuitively, the coarse-graining is unsatisfactory since it builds units whose constituent occasions have nothing to do with each other over the time-scale in question. Quantitatively, excess information over the obvious partition  $\mathcal{P}$  of the system into two parts is 0 bits. It is easy to show  $\xi \leq 0$  for any disjoint units. By comparison, the coarse-grainings in panels CD, which respect the grid structure, both generate positive excess information.

Figure 6: Detecting spatial organization. Units are the cells in the red (thick-edged) and gray (filled) squares at  $t = 0$  and  $t = 1$  respectively; other occasions are extrinsic noise. (A):  $\xi = 0$ . The coarse-graining groups non-interacting occasions into units. (B):  $\xi < 0$ . A blank grid is highly redundant. (CD):  $\xi > 0$ . Gliders perform interesting information-processing.

Thus we find that not only does our information-theoretic camera have an automatic focus, it also detects when processes hang together to form a single coherent scene.

**Excess information detects gliders.** Blank stretches of grid, Fig. 6B, are boring. There is nothing going on. Are interesting patches of grid quantifiably distinguishable from boring patches?

Excess information distinguishes blank grids from gliders:  $\xi$  on the blank grid is negative, Fig. 6B, since the information generated by the cells is redundant analogous to Fig. 3C. By contrast,  $\xi$  for a glider is positive, Fig. 6CD, since its cells perform synergistic categorizations, similarly to Fig. 3D. Glider trajectories are also captured by excess information: varying the location of the red units (at  $t = 0$ ) around the gray units we find that  $\xi$  is maximized in the positions shown, Fig. 6CD, thus expressing the rightwards and downwards motions of the respective gliders.

Returning to the camera analogy, blank patches of grid fade into (back)ground or are (transparent) channel, whereas gliders are highlighted front and center as units.

### Application: Hopfield networks

Hopfield networks embed energy landscapes into their connectivity. For any initial condition they tend to one of few attractors – troughs in the landscape (Hopfield, 1982; Amit, 1989). Although cells in Hopfield networks are quite different from neurons, there is evidence suggesting neuronal populations transition between coherent distributed states similar to attractors (Abeles et al., 1995; Jones et al., 2007).

$t$	output		INT: $B \rightarrow B$		EXT: $A \rightarrow B$	
	$A$	$B$	$ei$	$\max \xi$	$ei$	$\max \xi$

6	10101010	10101010	<b>2.42</b>	<b>0.10</b>	0.31	0.04

Table 1: Analysis of unidirectionally coupled Hopfield networks  $A \rightarrow B$  each containing 8 cells. The networks and coupling embed attractors  $\{00001111, 00110011, 01010101\}$  and their mirrors. Temperature is  $T = 0.25$ . A sample run is analyzed using two coarse-grainings: INT captures  $B$ 's effect on itself and EXT captures  $A$ 's effect on  $B$ ; see text.

Attractors are population level phenomena. They arise because of interactions between groups of cells – no single cell is responsible for their existence – suggesting that coarse-graining may reveal interesting features of attractor dynamics.

**Effective information detects causal interactions.** Table 1 analyzes a sample run of unidirectionally coupled Hopfield networks  $A \rightarrow B$ . Network  $A$  is initialized at an unstable point in the energy landscape and  $B$  in an attractor.  $A$  settles into a different attractor from  $B$  and then shoves  $B$  into the new attractor over a few time steps. Intuitively,  $A$  only exerts a strong force on  $B$  once it has settled in an attractor and before  $B$  transitions to the same attractor. Is the force  $A$  exerts on  $B$  quantitatively detectable?

Table 1 shows the effects of  $A$  and  $B$  respectively on  $B$  by computing  $ei$  for two coarse-grainings constructed for each transition  $t \rightarrow t + 1$ . Coarse-graining INT sets cells in  $B$  at  $t$  and  $t + 1$  as units and  $A$  as extrinsic noise. EXT sets cells in  $A$  at  $t$  and  $B$  at  $t + 1$  as units and fixes  $B$  at time  $t$  as ground.

INT generates higher  $ei$  for all transitions except  $1 \rightarrow 2 \rightarrow 3$ , precisely when  $A$  shoves  $B$ . Effective information is high when an output is sensitive to changes in an input so it is unsurprising that  $B$  is more sensitive to changes in  $A$  exactly when  $A$  forces  $B$  out from one attractor into another. Analyzing other sample runs (not shown) confirms that  $ei$  reliably detects when  $A$  shoves  $B$  out of an attractor.

**Macroscopic mechanisms depend on the ground.** Fixing the ground incorporates population-level biases into a coarse-grained cellular automaton's information-processing.

The ground in coarse-graining EXT (i.e. the output of  $B$  at  $t - 1$ ) biases the mechanisms of the units in  $B$  at time  $t$ . When the ground is an attractor, it introduces tremendous inertia into the coarse-grained dynamics since  $B$  is heavily biased towards outputting the attractor again. Few inputs from  $A$  can overcome this inertia, so if  $B$  is pushed out of an attractor it generates high  $ei$  about  $A$ . Conversely, when  $B$  stays in an attractor, e.g. transition  $5 \rightarrow 6$ , it follows its internal bias and so generates low  $ei$  about  $A$ .

**Excess information detects attractor redundancy.** Following our analysis of gliders, we investigate how attractors are captured by excess information. It turns out that  $\xi$  is negative in all cases: the functional dependencies within Hopfield networks are redundant. An attractor is analogous to a blank Game of Life grid where little is going on. Thus, although attractors are population-level phenomena, we exclude them as emergent processes.

**Excess information expresses attractor transitions.** We therefore refine our analysis and compute the subset of units at time  $t$  that maximize  $\xi$ ; maximum values are shown in Table 1. We find that the system decomposes into pairs of occasions with low  $\xi$ , except when  $B$  is shoved, in which case larger structures of 5 occasions emerge. This fits prior analysis showing transitions between attractors yield more integrated dynamics (Balduzzi and Tononi, 2008) and suggestions that cortical dynamics is metastable, characterized by antagonism between local attractors (Friston, 1997).

Our analysis suggests that *transitions* between attractors are the most interesting emergent behaviors in coupled Hopfield networks. How this generalizes to more sophisticated models remains to be seen.

## Emergence

The examples show we can quantify how well a graining expresses a cellular automaton's dynamics. Effective information detects glider trajectories and also captures when one Hopfield network shoves another. However,  $ei$  does not detect whether a unit is integrated. For this we need excess information, which compares the information generated by a mechanism to that generated by its submechanisms. Forming units out of disjoint collections of occasions yields  $\xi = 0$ . Moreover, boring units (such as blank patches of grid or dead-end fixed point attractors) have negative  $\xi$ . Thus,  $\xi$  is a promising candidate for quantifying emergent processes.

This section formalizes the intuition that a system is emergent if its dynamics are better expressed at coarser spatiotemporal granularities. The idea is simple. Emergent units should generate more excess information, and have more excess information generated about them, than their sub-units. Moreover emergent units should generate more excess information than *neighboring* units, recall Fig. 4.

Stating the definition precisely requires some notation. Let  $\text{src}_{v_l} = \{v_l\} \cup \{v_k | k \rightarrow l\}$  and similarly for  $\text{trg}_{v_l}$ . Let  $\mathcal{J}$  be a subgraining of  $\mathcal{K}$ , denoted  $\mathcal{J} \prec \mathcal{K}$ , if for every  $\mathbf{U}_j \in \mathcal{J}$  there is a unit  $\mathbf{U}_k \in \mathcal{K}$  such that  $\mathbf{U}_j \subsetneq \mathbf{U}_k$ . We compare mechanism  $\mathbf{m} \subset \mathcal{K}$  with its subgrains via

$$\xi_{\mathcal{K}/\mathcal{J}}(\mathbf{m}, x_{out}) := ei_{\tilde{\mathcal{K}}}(\mathbf{m}, x_{out}) - \sum_{v_j \in \mathcal{J}} ei_{\tilde{\mathcal{J}}}(\mathbf{m}^j, x_{out}),$$

where  $\mathbf{m}^j = \mathbf{m} \cap \text{src}_{v_j}$  and  $ei_{\tilde{\mathcal{K}}}$  signifies effective information is computed over  $\mathcal{K}$  using micro-alphabets.

**Definition (emergence).** Fix cellular automaton  $X$  with output  $x_{out}$ . Coarse-graining<sup>2</sup>  $\mathcal{K}$  is emergent if it satisfies conditions E1 and E2.

E1. Each unit  $\mathbf{U}_l \in \mathcal{K}$  generates excess information about its sources and has excess information generated about it by its targets, relative to subgrains  $\mathcal{J} \prec \mathcal{K}$ :

$$0 < \xi_{\mathcal{J}/\mathcal{K}}(\text{src}_{\mathbf{U}_l}, x_{out}) \text{ and } 0 < \xi_{\mathcal{J}/\mathcal{K}}(\text{trg}_{\mathbf{U}_l}, x_{out}). \quad (8)$$

E2. There is an *emergent* subgrain  $\mathcal{J} \prec \mathcal{K}$  such that (i) every unit of  $\mathcal{K}$  contains a unit of  $\mathcal{J}$  and (ii) neighbors  $\mathcal{K}'$  (defined below) of  $\mathcal{K}$  with respect to  $\mathcal{J}$  satisfy

$$\xi_{\mathcal{J}/\mathcal{K}'}(\text{src}_{\mathbf{U}'}, x_{out}) \leq \xi_{\mathcal{J}/\mathcal{K}}(\text{src}_{\mathbf{U}}, x_{out}) \quad (9)$$

for all  $\mathbf{U} \in \mathcal{K}$ , and similarly for  $\text{trg}$ 's.

If  $\mathcal{K}$  has no emergent subgrains then E2 is vacuous.

Grain  $\mathcal{K}'$  is a *neighbor* of  $\mathcal{K}$  with respect to  $\mathcal{J} \prec \mathcal{K}$  if for every  $\mathbf{U} \in \mathcal{K}$  there is a unique  $\mathbf{U}' \in \mathcal{K}'$  satisfying

- N1. there is a unit  $T \in \mathcal{J}$  such that  $T \subset \mathbf{U}, \mathbf{U}', \text{src}_T \subset \text{src}_{\mathbf{U}}, \text{src}_{\mathbf{U}'}$  and similarly for  $\text{trg}$ ; and
- N2. the alphabet of  $\mathbf{U}'$  is no larger than  $\mathbf{U}$ :  $|\prod_{k \in \mathbf{U}'} A_k| \leq |\prod_{l \in \mathbf{U}} A_l|$ , and similarly for the combined alphabets of their sources and targets respectively.

The graining  $\mathcal{E}_X$  that best expresses  $X$  outputting  $x_{out}$  is found by maximizing normalized excess information:

$$\mathcal{E}_X(x_{out}) := \arg \max_{\{\mathcal{K} | \text{emergent}\}} \frac{\xi(\mathcal{K}, x_{out})}{\mathcal{N}_{\mathcal{P}_{MIP}}^{\mathcal{K}}}. \quad (10)$$

Here,  $\mathcal{N}_{\mathcal{P}_{MIP}}^{\mathcal{K}}$  is the normalizing constant found when computing the minimum information partition for  $\mathcal{K}$ .

**Some implications.** We apply the definition to the Game of Life to gain insight into its mechanics.

Condition E1 requires that interactions between units and their sources (and targets) are synergistic, Fig. 6CD. Units that decompose into independent pieces, Fig. 6A, or perform highly redundant operations, Fig. 6B, are therefore not emergent.

Condition E2 compares units to their neighbors. Rather than build the automaton's spatial organization directly into the definition, neighbors of  $\mathcal{K}$  are defined as coarse-grainings whose units overlap with  $\mathcal{K}$  and whose alphabets are no bigger. Coarse-grainings with higher  $\xi$  than their neighbors are closer to focal points, recall Fig. 4 and Fig. 6CD, where  $\xi$  was maximized for units respecting glider trajectories. An analysis of glider boundaries similar in spirit to this paper is (Beer, 2004).

<sup>2</sup>Ground output  $s^G$  is  $x_{out}$  restricted to ground occasions.

Finally, Eq. (10) picks out the most expressive coarse-graining. The normalization plays two roles. First, it biases the optimization towards grainings whose MIPs contain few, symmetric parts following (Balduzzi and Tononi, 2008). Second, it biases the optimization towards systems with simpler macro-alphabets. Recall, Fig. 5, that coarse-graining produces more symbolic interactions by decreasing the size of alphabets. Simplifying alphabets typically reduces effective and excess information since there are less bits to go around. The normalization term rewards simpler levels of description, so long as they use the bits in play more synergistically.

## Discussion

In this paper we introduced a flexible, scalable coarse-graining method that applies to any cellular automaton. Our notion of automaton applies to a broad range of systems. The constraints are that they (i) decompose into discrete components with (ii) finite alphabets where (iii) time passes in discrete tics. We then described how to quantify the information generated when a system produces an output (at any scale) both as a whole and relative to its subsystems. An important feature of our approach is that the output  $x_{out}$  of a graining is incorporated into the ground and also directly influences  $ei$  and  $\xi$  through computation of the actual repertoires. Coarse-graining and emergence therefore capture some of the *suppleness* of biological processes (Bedau, 1997): they are context-dependent and require many *ceteris paribus* clauses (i.e. background) to describe.

Investigating examples taken from Conway's Game of Life and coupled Hopfield networks, we accumulated a small but significant body of evidence confirming the principle that *expressive coarse-grainings generate more information relative to sub-grainings*. Finally, we provisionally defined emergent processes. The definition is provisional since it derives from analyzing a small fraction of the possible coarse-grainings of only two kinds of cellular automata.

Hopfield networks and the Game of Life are simple models capturing some important aspects of biological systems. Ultimately, we would like to analyze emergent phenomena in more realistic models, in particular of the brain. Conscious percepts take 100-200ms to arise and brain activity is (presumably) better expressed as comparatively leisurely interactions between neurons or neuronal assemblies rather than much faster interactions between atoms or molecules (Tononi, 2004). To apply the techniques developed here to more realistic models we must confront a computational hurdle: the number of coarse-grainings that can be imposed on large cellular automata is vast. Nevertheless, the approach developed here may still be of use. First, manipulating macro-alphabets provides a method for performing approximate computations on large-scale systems. Second, for more fine-grained analysis, initial estimates about which coarse-grainings best express a system's dynamics can be

fine-tuned by comparing them with neighbors.

**Acknowledgements.** The author thanks Dominik Janzing for many useful comments on an earlier draft, Giulio Tononi for stimulating conversations and Virgil Griffiths for emphasizing the importance of excess information.

# Walking, Hopping and Jumping: A Model of Transcription Factor Dynamics on DNA

David J. Barnes<sup>1</sup> and Dominique Chu<sup>1</sup>

<sup>1</sup>School of Computing, University of Kent, CT2 7NF, Canterbury, UK  
{d.j.barnes, d.f.chu}@kent.ac.uk

## Abstract

We present a model of how transcription factors scan DNA to find their specific binding sites. Following the classical work of Winter et al. (1981), our model assumes two modes of transcription factor dynamics. Adjacent moves, where the proteins make a single step movement to one side, or short walks where the transcription factors slide along the DNA several binding sites at a time. The purpose of this article is twofold. Firstly, we discuss how such a system can be efficiently modelled computationally. Secondly, we analyse how the mean first binding times of transcription factors to their specific time depends on key parameters of the system.

## Introduction

Regulation of gene activity can be understood as a computational process, in the sense that the cell reacts to changes in the environment by changing its internal states. There are several mechanisms the cell can use to make such internal changes. One important such mechanisms is the regulation of genes. In bacteria, gene regulation often involves the binding of regulatory proteins, so called *transcription factors* (TFs), to particular binding sites on the DNA.

One aspect that has commanded significant attention from bioscientists, physicists and systems biologists is the time required for regulatory proteins to find their target binding site on the genome. The problem is as follows: In order to turn a gene on (or indeed repress it) the TF needs to locate a specific binding site. The problem is that TFs are “sticky” to all parts of the DNA. When binding to the DNA a TF actually binds to an  $l$ -long sequence of nucleotides. The binding strength depends on the match between the bound sequence and an optimal pattern which represents the sequence of the specific binding site. The closer the match, the higher the affinity. While the binding affinity to specific sites is much higher than to most non-specific sites, the contribution of the latter is still significant enough to potentially “distract” a TF from locating its specific site. Furthermore, there are millions of non-specific sites and only few of the specific and active sites for each particular TF. Therefore, even though a TF spends very little time being bound to each of the non-specific sites, it may take a significant time to sample all

of them before the specific site is eventually found. The process of a TF finding its specific binding site necessarily limits the speed of a biological computation.

This problem, which has been known about for a long time, was first addressed by Winter et al. (1981), who proposed a random walk model of facilitated diffusion. The idea of this model is that the TF performs a mixed 1D and 3D random walk. The 1D random walk explores a small adjacent neighborhood of DNA, while the 3D random walk allows the TF to explore far-away, unconnected parts of the genome. It has been suggested by Wunderlich and Mirny (2008); Slutsky et al. (2004) and Murugan (2009) that the most efficient exploration of the genome, in the sense that it offers the fastest location of the specific binding site, is achieved when the 3D and 1D components are weighted approximately equally.

Most of the above work has been analytical. There are also a number of other results available. In this article we will describe an approach to building an efficient computer simulation model of TFs finding their specific binding sites (Barnes and Chu (2010)). This new approach will allow realistically sized simulations, thus significantly expanding the scope of previous models. The essence of the efficiency of the model is a careful management of memory to make the problem scalable, regardless of genome occupancy.

## The Model

The movement dynamics of TFs involves a search across a discrete (but very high) number of spatially organised binding sites. This suggests the potential for an individual agent-based modelling approach. The environment of the TF agents is a non-metric space; that is, there is no measure of distance between the agents. Embedded in this space is the DNA itself, which is represented as a string of the symbols  $a, c, g, t$  with periodic boundary condition. For all simulations reported here we used the genome of *E.coli* K12 (The University of Wisconsin (2009)). At any given time, every agent is either bound to one of the binding sites of the genome, or suspended in the non-metric space. We think of the space as a ‘reservoir’ of currently unbound TFs.

We define two types of agents, namely focal and non-focal TFs. We are primarily interested in the former, yet the latter are important in that their presence on the DNA could interfere with the search dynamics of the focal TFs. The number of non-focal TFs is kept constant during a specific simulation run (for reasons of computational efficiency), whereas the focal TFs are created and degraded with user-defined rates, hence particle numbers within the cell fluctuate over time.

Focal TFs have a definite binding *motif*  $\mathbf{m}$  that is used to determine their binding energy and, hence, their mean binding time at every DNA binding site in the model. If the length of the binding motif  $\mathbf{m}$  is  $l$  then the binding free energy to a particular sequence is calculated as follows:

$$F_s = \sum_{i=1}^l \omega_i \delta_{m_i, s_i} \quad (1)$$

Here,  $m_i$  is the  $i$ -th entry of the motif  $\mathbf{m}$ ,  $s_i$  the corresponding base of the actual binding sequence  $\mathbf{s}$  and  $\omega_i$  the empirically determined weighting factor of the binding motif. In contrast, non-focal TFs do not have specific binding sites; rather, they share low, position-dependent affinities to all sites on the DNA. Rather than calculating the binding energies dynamically, the affinity values for both types of TF are pre-calculated for every position on the DNA and stored in arrays of the same length as the DNA, making binding-time calculation very efficient.

The model update algorithm is event based, with three main classes of event available at each step:

- Create a focal TF.
- Bind a TF of either type to the DNA.
- Unbind a bound TF from the DNA.

Unbind events can result in complete unbinding into the reservoir or short, local 1D movements. Essential for the reliability of the model is to design the update algorithm so that the behaviour of the model is correct with respect to the choice of parameters (in the sense that it reproduces the statistics implied by the various binding and unbinding rates). To achieve this, we have adapted the Gillespie algorithm (Gillespie (1977)) to schedule events.

On every event, regardless of its class, only a single TF is updated. Breaking down the event classes in more details: an update consists of one of the following actions:

- A new focal TF is created and might attempt to bind.
- A TF binds from the reservoir to the DNA.
- A bound TF unbinds from the DNA into the reservoir.
- A bound TF moves to an adjacent binding site on the DNA.

- A bound TF makes a short move, i.e., binds with a uniform probability to an available binding site in the vicinity of its current site. The range of what counts as “vicinity” is user determined.
- A bound TF is destroyed.

## Scheduling of events

At model initialization all non-focal TFs are created and seeded onto random locations on the DNA via bind events at time zero. If there is insufficient space then the excess ends up in the reservoir. Then the creation times of all focal TFs are determined according to a user-defined rate, and creation events scheduled accordingly. Their lifetime is also determined at creation with a random number drawn from an exponential distribution with a mean of 1 over the deletion rate.

When its creation event occurs, a focal TF will immediately attempt to bind to a site on the genome with a user-defined probability; any such attempt is successful with a probability  $p = N_{\text{free}}/N_{\text{range}}$  where  $N_{\text{range}}$  is the total number of binding sites in range and  $N_{\text{free}}$  is the number of unoccupied sites in that range. We specify  $N_{\text{range}}$  because the initial bind attempt for a focal TF takes place within a limited, user-defined birth range on the DNA. This models the effect that (in bacterial cells) transcription and translation are performed in one step and hence proteins are produced close to their gene.

If the newly-created TF does not bind, then it is placed in the reservoir and may have the opportunity to attempt a general bind (i.e., one over the full range of the DNA) at a later time. The range restriction only applies to the initial binding attempt of a focal TF.

## Binding events

General binding is used both to seed initial occupancy of the DNA with non-focal TFs, and to support binding of both types of TF from the reservoir. A random available binding site is chosen from the full length of the DNA.

At the completion of every event, there is a probability that an unbound TF might attempt to bind from the reservoir. The time to the bind event is drawn from an exponential distribution with a mean of 1 over a value that depends upon the number of unbound TFs  $T_u$ , the number of available binding sites  $N_{\text{free}}$  along the full range of the DNA, and a constant factor  $k$ :

$$P(\text{bind}) = (k N_{\text{free}} T_u) \quad (2)$$

A new binding event will only be scheduled if it would occur before the next already scheduled event. This is because the binding probability depends on the current availability of binding sites which generally changes over time.

## Unbinding events

The duration time of a DNA-protein bond depends on the affinity of the type of TF for its binding site; specifically, for focal TFs this affinity is determined from equation 1. It is drawn from a Poisson distribution with mean  $\mu$ .

$$\mu = \exp\left(-\frac{F_s}{kT}\right)$$

Here  $k$  is the Boltzmann constant and  $T$  the absolute temperature. Binding from the reservoir onto the DNA is determined stochastically with a given user-determined rate.

At every unbind event, the next state of the TF is determined stochastically. Assuming that the TF has not reached the end of its life (in which case it would be destroyed), with a user-defined probability one of the following options will apply to it:

- the TF will attempt to make a one place move left or right (an immediately scheduled bind event);
- the TF will attempt a short move within a user-defined range either side of the previous binding site (an immediately scheduled bind event);
- the TF goes into the reservoir.

Either move could fail, due to roadblocks, and lead to the TF going into the reservoir. It should be clear from the above description that, on each iteration, the heart of the event loop is primarily concerned with: placing a TF on the DNA; removing a TF from the DNA; or both. Therefore, identifying free sections on the DNA is a potential performance bottleneck that could prevent scaling of the method to realistic sizes of both DNA and numbers of TFs.

## The memory model

The key to efficient implementation of binding and movement is the fast identification of available binding sites — i.e., not just empty bases but runs of bases that are at least as long as the binding motif (see eq 1) and can thus support binding of a TF. A naive representation of the DNA might be an array of Boolean values, one for each possible site, recording whether a site is currently occupied by a bound TF or not. In this implementation, an attempt to bind would involve the generation of a random number within the desired location range and a check as to whether that location is free or not. If it is not free then options might be: abandoning the attempt immediately; searching from that location in one or other direction until a free site is found; or identifying a fresh random location and repeating the process until a free site is found. While simple to implement, the weakness of this approach is immediately clear as the time to find a free location is dependent upon the occupancy of the DNA. Indeed, even when there are plenty of free individual bases, there are no guarantees that a long enough consecutive run

will exist to allow a TF to bind, and the approach outlined above must ensure that a search in vain will ultimately terminate.

Using this scheme the time to locate a free binding site depends on the occupancy of the DNA, and scales poorly with the size of the genome. In this model we therefore use a different approach that can find binding sites within a time independent of the occupancy. Rather than an unstructured array of Boolean status values we maintain a data structure that records all the remaining bindable sections of the DNA, as *(position, length)* pairs. The DNA is modeled as a 1D wrap-around structure. Note that because binding and unbinding occur at irregular intervals, sections of binding sites are occupied and freed according to no particular regular pattern. The resulting space management problem is akin to *dynamic storage allocation* in program runtime environments (Knuth (1997)), as opposed to *stack* (last-in, first-out) memory management, for instance. A significant difference, however, is that traditional allocation algorithms, such as *first fit* and *best fit*, are inapplicable in this context, because the memory manager must always allocate a particular section of free space that has been selected by the bind event, rather than having a free choice. In common with dynamic memory allocation, available space quickly becomes “fragmented”. For instance, consider a run of  $l + n$  unoccupied sites, where  $l$  is the length of a TF to be bound and  $n \geq l$  (Figure 2a). This sequence offers  $n + 1$  potential binding sites before a bind but anywhere between 0 and  $n - l + 1$  sites after the bind, depending on where the bind takes place within the run and the size of  $n$  in comparison to  $l$ . If the TF were to bind across the middle of the section then the two fragments either side may well be too short to support another TF (Figure 2b). As a result, the data structure recording bindable sections must be supplemented by a similar data structure recording unbindable fragments. For both we use the `set` associative container from the C++ STL (Meyers (2001)), which provides efficient access via its key which, in our case, is the binding position. Note that a fragment resulting from the bind of one TF may become usable before that particular TF unbinds — as a result of the earlier bound TF occupying the adjacent section at the other end of the fragment becoming unbound (Figure 2c). Indeed, most of the complexity of the memory management occurs during the bind-unbind cycle, at the point where a TF unbinds and the section it occupies becomes available again. Before being returned to the set of available sections it must be reunited with any fragments at either end. In addition, the newly freed section may now be contiguous with another already available section, in which case the two must be coalesced into one.

## Methods

All simulations in this article were performed by starting with an empty wraparound DNA of length 4639675 at time

Figure 1: A histogram of the binding free energies as calculated from eq. 1. The energies are Gaussian distributed.

Figure 2: DNA section illustrating fragmentation and de-fragmentation during TF binding and unbinding; a) Two bound TFs, fragments and an available section; b) A third TF binds, resulting in two new fragments; c) A TF unbinds, fragments become available again.

0. Upon starting, the simulation protein was created with a rate of 0.01. The degradation rate of protein was 0.0009. Each simulation was run for a maximum of  $10^9$  time units, but was halted as soon as a TF was bound to the specific binding site at position 4540692 on the DNA. The halting time was taken as the mean first binding time (MFBT) referred to below. For each set of parameters the MFBT was calculated from 10 independent simulations (unless specified otherwise). In the graphs below, each point indicates the MFBT where the mean has been taken over the set of simulations that had been performed. Error-bars and standard deviation are not indicated in the graphs to preserve legibility. In nearly all experiments we performed, the standard deviation is comparable to the mean, indicating that typical binding times deviate significantly from the mean.

The source code of the program used here is available for free download.<sup>1</sup>

## Results

One of the main variables to consider is the time the TF requires to reach its specific site. For a single random walker it is expected that MFBT scales with the square root of the distance. In the case of an ensemble walking this may be different. We decided to check this. To this end we performed a number of experiments with the following setup: We chose a synthesis site at which the TFs were produced. This has the effect that the TFs would attach at random to the binding site within a specified window. This introduces a stochastic element into the simulation, in the sense that not all TFs start from the same site. Some will start closer to the specific site, some from farther away. This choice has another effect. It limits the number of TFs that can attach to the DNA per time unit. The reason is that, upon binding to the DNA, TFs either occupy the binding sites within the initial binding window or they are released into the cytoplasm (represented by the “reservoir” in our model). If all sites within this window are occupied, no further TFs can bind and newly synthesised TF will always be released into the cytoplasm. We set the parameters such that no binding from the cytoplasm to the DNA is possible; hence, for the purpose of our simulation, once a TF unbinds from the DNA it is, in effect, lost forever. We found that the initial binding window is a strong restriction on the number of bound TFs.

We first performed a number of simulations with the initial binding window equal in size to the DNA. The effect of this is that newly created TFs will bind anywhere on the DNA. We allow the TFs to perform short moves of length up to 50 binding sites at a time; adjacent moves happen with a probability of 0. In this case we would predict that the MFBT is independent of the location of the synthesis site, but we would expect that the MFBT decreases as the TFs can travel faster, that is a higher short move length should lead to lower MFBTs. We varied both the probability of short moves and the site where TFs are synthesized. Figure 3 summarises the results of these simulations and confirms that the synthesis site is irrelevant, as expected. The graph shows the MFBT when all movements are only adjacent neighbor moves ( $P = 1$ ), they are all short move events ( $P = 0$ ) and an in-between case ( $P = 0.8$ ). For other values of  $P$  we found that the MFBT always increases with increasing  $P$ . As can be seen from figure 3 the difference between the MFBTs for extreme cases of  $P$  are at the order of a magnitude.

In bacteria translation and transcription are closely inter-linked. This means that protein tends to be made in close spatial proximity to the gene that codes for the particular protein. Following gene synthesis there is thus an increased chance that a TF binds to a particular local region of the DNA. We investigate the effect of this on the MFBT by varying the location of the initial binding window. Figure 4 shows a number of simulations with a window size of 40 (20 on each side of an assumed protein synthesis site). Such a

Figure 3: The mean first binding time to reach a particular specific site as a function of the short move distance. The window size equals the size entire genome. The short move length was set to 50 in these simulations.

Figure 4: The mean first binding time to reach a particular specific site as a function of the short move distance. The short move probability was set to 0.9.

small preferred binding window is, admittedly, biologically unrealistic. However, it was chosen for practical considerations relating to the simulation speed. We found a strong dependence of the MFBT on the protein synthesis location as summarised in figure 4.

From these experiments it seems that a higher short move probability speeds up the search process. However, we would expect that the importance of this effect depends on the proximity of the synthesis site to the specific binding site. If the binding site is very close to the synthesis site, then one would conjecture that large step sizes will tend to “overshoot,” that is they will simply miss the specific site during the movement. With larger initial distances this overshoot will happen as well, but TFs will move faster into the proximity of the specific site, hence counteracting this effect.

Figure 5: The mean first binding time to reach a particular specific site as a function of the short move distance. The short move probability was set to 0.9.

We performed a variant of the above experiments to understand this in more detail. The graph in figure 5 shows simulations where we kept the initial binding site fixed at an offset of  $\pm 3000$  binding sites from the specific site. The  $x$ -axis shows the short move length in the simulation and the sign of the  $x$ -axis indicates the centre of the initial binding site. So, for example the point marked at  $x = -100$  represents a simulation with an offset of the initial binding site of  $-3000$  from the specific binding site, and a short move length of 100. In these simulations each point represents the average MFBT over 1000 simulation experiments. The graph shows values for 3 different adjacent move probabilities, corresponding to all movements are short-moves, 90% of all events are short-move events and 10% of all move events are short move events.

The graph is somewhat complex to interpret, but shows that the MFBT falls faster than exponential with the short move length. For  $P = 0$  and  $P = 0.9$  the MFBT decreases by several orders of magnitude as the short move length increases from 20 to 100. When the short move length is smaller than 20, then irrespective of the value of  $P$  in the simulations shown here the MFBT is larger than the maximum simulation time of  $10^9$  time units.

A closer look at the simulation results, particularly at figure 5 reveals that the MFBT is asymmetric around the specific binding site. When the binding site is to the right of the specific site (i.e., higher id-numbers in the coordinate system used here), then the MFBT tends to be lower than when the TF is synthesised to the left. This effect is clearly illustrated in figure 5. Particularly for high short move length values there is a clear difference between the two synthesis sites. For example, when the short move length is 180, then for the parameters used in the figure the difference between the MFBTs amounts to nearly a factor of 2.

The underlying cause of the difference appears to be the

Figure 6: Same as figure 5, but with  $P = 0$  and with an offset of  $\pm 100$ .

presence of 3 further specific binding sites to the right of the focal site we are interested in. These three additional specific binding sites are in very close spatial proximity to the focal site with offsets of 18, 303 and 321 binding sites respectively. One can think of the dynamics as follows: When a TF binds to one of the 4 binding sites, then it acts as a reflecting boundary for random walkers in the area, confining random walkers within the area of the specific binding sites. This has the net effect of reducing the MFBT for the random walkers.

In figure 5 it appears that the longer the sliding distance, the shorter the MFBT. This is somewhat counter-intuitive. We would expect that there is an optimum sliding distance, which allows fast approach of the specific binding site, while balancing this with the problem of over-shooting the specific site. Within the short move distances considered in figure 5 such an optimum is not apparent. However, we would expect that such an optimum short move distance depends on the distance of the synthesis site from the specific site; the closer the synthesis site, the shorter the optimal short move distance. To check this we performed another set of experiments varying the short move distance, but with synthesis sites located at an offset of  $\pm 100$ . Figure 6 shows the results. It is apparent that there is a clear minimum MFBT for both offsets, as expected.

## Discussion and Conclusion

In this contribution we have presented a model that supports the efficient simulation of the process of TFs finding their specific binding sites. One of the problems that we had identified was that realistic simulations are computationally extremely demanding. For this reason, modeling of specific binding site localisation has been restricted to mathematically tractable but unrealistic models. Here we have made the first steps towards a computationally feasible implementation. One of the bottlenecks we have identified is the lo-

calisation of free binding sites on the DNA. By adapting approaches from dynamic memory allocation we were able to achieve speedups with respect to a naive algorithm of many orders of magnitude.

Apart from finding an efficient simulation implementation, we found that the MFBT depends in a complicated way on the short move distance, the synthesis site, but also the local configuration of the binding sites. Our simulations are a significant extension (although in simulation) to the analytical results developed by both Murugan and Mirny *et al.* The picture emerging from these simulations is that the situation is significantly more involved than suggested by these previous articles. For example: One of the conclusions by Murugan was that there is an optimal division between adjacent moves and short moves. We could not reproduce this in our setup. Instead we found that, up to the range we investigated, short moves are generally faster and more efficient than adjacent moves. We do not mean to imply that their conclusions are wrong. However, it is clear that the conclusions of various models are not robust with respect to variations of underlying assumptions. This is normally a worrying sign in modelling.

This suggests that a more thorough investigation of this system is necessary, in order to come to a clear understanding of how previous mathematical results relate to the simulation results obtained here.

## Abstract

We introduce a fast cellular automata model for the simulation of surfactant dynamics based on a previous model by Ono and Ikegami (2001). Here, individual lipid-like particles undergo stochastic movement and rotation on a two-dimensional lattice in response to potential energy gradients. The particles are endowed with an internal structure that reflects their amphiphilic character. Their head groups are weakly repelled by water whereas their hydrophobic tails cannot be readily hydrated. This leads to the formation of a variety of structures when the particles are placed in solution. The model in its current form compels a myriad of potential self-organisation experiments. Heterogeneous boundary conditions, chemical interactions and an arbitrary diversity of particles can easily be modelled. Our main objective was to establish a computational platform for investigating how mechanisms of lipid homeostasis might evolve among populations of protocells.

## Introduction

The debate concerning the containers within which the first biochemistries developed is hotly contested. One uncontroversial observation however, is that Nature has since fixed upon a single class of molecule to use as the barrier between cell contents and the external environment, be it the intercellular space or the outside world. These special molecules - lipids - possess the crucial property of being amphiphilic, they contain both hydrophilic and hydrophobic groups. Amphiphilic molecules are an example of a surfactant, a substance which reduces the interfacial tension between two fluids (we shall use the terms amphiphile, surfactant and lipid interchangeably). They are thus endowed with an ability to arrange themselves into meso-scale structures when placed in solution. The shapes of these structures reflect the systems' attempts to minimise contact between hydrophobic groups within the amphiphiles, and water molecules. One such structure, the vesicle, can be conveniently used to separate one aqueous environment from the surrounding water. It is this molecular device that organisms have adopted as a means of separating the inner cell space from its exterior. All nutrients and waste products must pass through this barrier in order to carry out their function within a cell. The

membrane must also grow, sever, re-connect and undergo various other transformations during the cell cycle. Other lipid membranes separating organelles from the intracellular space must also adopt various shapes and curvatures in order to maximise their function. Given the tremendous importance of membranes both during the early stages of the evolution of life and in contemporary organisms, it is easy to justify the pursuit of a complete understanding of amphiphile dynamics.

The electrostatic interactions between the constituents of lipid molecules are fairly well understood as are the equations of motion for the behaviour of such molecules in solution. Furthermore, the equilibrium properties of surfactant-water-oil systems have been analysed using a lattice model first introduced by Widom (1986). Having successfully reproduced some key features of surfactant phase diagrams, Widom's simple lattice model as well as other spin-based models (so-called due to their being isomorphic to a spin- $\frac{1}{2}$  Ising model), stimulated a profusion of investigations to be carried out both analytically and through Monte Carlo simulation (Larson et al., 1985). For a summary of the research performed during this period, see also the review of Kawakatsu et al. (1994). Despite these successes, there remain significant analytical obstacles to the complete understanding of more complex, biologically relevant lipid systems (for example, if we wish to include processes such as the synthesis and decay of lipids through metabolic pathways). Life is the antithesis of thermodynamic equilibrium, and exhibits highly non-linear dynamical behaviour to boot. These factors, among others, have presented what appear to be insurmountable barriers to a pure analytical understanding of the higher level systems of molecular biology. Instead we must, for the time being at least, look to computational methods. Even numerical integration of the equations of motion is a daunting task. Real systems of interest involve massive numbers of molecules, and interesting dynamic behaviour occurs over time scales which are much longer than typical numerical integration steps. Therefore models derived from first principles which solve the exact system of equations (molecular dynamics) are very expensive in terms

of computational resources. Multi-scale and hybrid models have been put forward by Ayton and Voth (2002) and Lyubartsev (2005) for example, but simulations over longer time scales and mesoscopic length scales with the potential for variable environments and boundary conditions are still relatively rare.

The popularisation of cellular automata (CA) models has given birth to a family of simulation techniques which have shown considerable promise for modelling complex systems such as amphiphile solutions (Kier et al., 1999; Nilsson and Rasmussen, 2003; Rothman and Zaleski, 2004). CAs are discrete time and space models in which all interactions occur on a local scale. These properties allow CAs to be much less computationally demanding than traditional numerical schemes. The lattice and discretisation constraints of CAs can cause problems with respect to invariance under geometric transformations but there is one class which has been shown to mimic reality with surprising effectiveness. So-called lattice gas models simulate hydrodynamics by allowing a set of particles to move and collide on a lattice. The rules of interaction are defined such that mass and momentum are conserved and one can derive the Navier-Stokes equations from the microdynamical rules of the CA (Frisch et al., 1986). The basic lattice gas has been extended for a variety of applications including the fluid dynamics of water-oil-surfactant mixtures (Boghossian et al., 1996, 2000; Mayer et al., 1997). Both of these models were successful in re-creating some key lipid phases and were later applied to more specific systems including, in the case of the model of Boghossian et al. (1996), self-reproducing micelles (Coveney et al., 1996), which showed impressive agreement with the experimental results of Bachmann et al. (1992).

In this investigation, we explored the abilities of a new CA for the simulation of amphiphile solution systems based upon the artificial chemistry model of Ono and Ikegami (2001). This model differs from the lattice gases mentioned above. Particles move in pursuit of potential energy minima, but they do not collide and exchange momentum. We perform this simplification of neglecting the individual particle momenta because we wish to focus on the self-assembly process and the meso-level dynamics of more complex systems with variable boundary conditions. By ignoring the explicit hydrodynamics of the system, the formulation of the model is greatly simplified as are the computational demands. We believe that the key dynamics of the self-assembly process are nevertheless retained.

An important feature of our simulations is the way in which surfactants are defined. Rather than a generic ‘membrane’ particle, we have applied a more explicit representation of the internal structure of amphiphiles. In addition, we introduced three different lipid species, each with its own geometry. Real cell membranes consist of many different lipid types. Some of them naturally form bilayers but there are also non-bilayer forming lipids present. The exact func-

tion of these non-bilayer lipids has been debated for many years and it is likely that they play several roles in the cellular performance (Lindblom et al., 1986). The stability, robustness and versatility of cell membranes derives in part from the homeostatic balance of the distribution of these varied lipid species (Beard et al., 2008). Therefore we aimed to endow our model with the additional freedom of having lipids with a range of membrane-forming properties. Our objective was to construct a platform which we could use to investigate the spontaneous evolution of lipid homeostatic mechanisms. Ono and Ikegami (2001) have already shown that simple cell-like entities arise spontaneously within their model framework. We aim to extend that model framework such that we can simulate not only the formation of protocells, but also the evolution by those protocells of mechanisms for balancing the lipid composition of their membranes. In our model, the geometry of vesicles (or protocell membranes) resulting from the spontaneous organisation process depends not only on environmental factors but also on the distribution of the different lipid species, since each species has its own preferred membrane curvature.

In this paper we wish to present the model in its current form as a tool for simulating an interesting and important class of complex system. As well as simulating the emergence of lipid homeostasis, the model could easily be modified to simulate complex reaction-diffusion or self-reproducing micellar systems, among others. We shall first give a brief description of the workings of the model, before describing the main results of our investigations so far. These will include simple phase separation of water and hydrophobic monomers, micelle formation, bilayer formation, ternary mixtures leading to monolayer formation and finally a set of hysteresis experiments. We shall then conclude with a discussion of the significance of these results before suggesting some relevant systems which will be simulated by our model in the future. Due to space restrictions, we shall not present a strong focus on the technical details of the model, instead we shall describe the most important features and highlight its phenomenological successes.

## Model Description

The mechanics of our model are essentially the same as those of Ono and Ikegami (2001); Ono (2005). The simulation domain is a 2-dimensional triangular lattice over which particles move and interact. An arbitrary number of particles can reside on each lattice site, and the boundaries of the lattice are periodic. The model proceeds via a standard metropolis algorithm (relaxation towards a global potential energy minimum). All interactions between possible particle pairs across all relative orientations are defined *a priori* in the form of a lookup table. Same site interactions consist of a strong excluded volume repulsion which is the same for all particle types and acts between all particle types. The nearest-neighbour interactions take several different forms.

All forces are repulsive but the strength depends on the physical properties of the two particles involved in the interaction. In order to approximate the effect of hydrogen bonding, water particles repel one another with almost negligible force. Hydrophobic monomers also repel each other weakly. There is a strong repulsion felt between water particles and hydrophobic monomers. This is due to the frustration of the surrounding water molecules, which are unable to satisfy all of their potential hydrogen bonds. Interactions involving surfactants are slightly more complicated.

The crucial differences between our version of the model and that of Ono and Ikegami (2001), are the structure and interactions of the surfactants. We make use of a more explicit representation of lipid particle geometry. Although the surfactants have internal structure, we do not model the harmonic motion of the individual molecular components. Each surfactant is represented as a rigid particle free only to rotate in discrete increments (reflecting the discrete nature and underlying symmetry of the lattice). The pairwise interactions between these particles are computed using the sum of a set of Lennard-Jones functions. These calculate Van der Waals forces for the four interactions between the hydrophilic heads and hydrophobic tails of all pairs of surfactants which are nearest neighbours. Physically, these four terms represent the dipole-dipole interaction between the polar head regions, the dipole-induced dipole interactions between the heads and hydrocarbon tails, and the induced dipole-induced dipole interaction between the two tail regions.

Figure 1: Equilibrium orientations of pairs of surfactant particles. a)  $M_1$  particles at adjacent lattice sites align with their tails closer than their heads due to their cone-like geometry. b) an  $M_2$  particle and an  $M_3$  particle prefer to align with an angle of  $\pi/6$  between their axes. This is due to the wider splay of the tails of  $M_3$  particles.

$M_1$  particles are modelled on detergent particles with single alkyl chains. This gives them a cone-like shape with a broader head region. Figure 1(a) shows a schematic illustration of their pairwise equilibrium configuration. The two  $M_1$  particles align with an angle of  $\frac{\pi}{3}$  between their vertical axes.  $M_2$  particles are based on lipids with double hydrocarbon chains giving them a cylindrical geometry. As a result

they prefer to align parallel with one another.  $M_3$  particles have broader tail regions, wider than their head groups. A second example of the equilibrium configuration of a pair of particles is shown in figure 1(b), which illustrates how the cylindrical  $M_2$  particle and the broad-tailed  $M_3$  particle prefer to align with one another. Since the  $M_2$  particle has a cylindrical geometry but the  $M_3$  particle has a broader tail region, these two particles prefer to align with an angle of  $\frac{\pi}{6}$ . The other equilibrium configurations are defined in a similar way, e.g. an angle of  $\frac{\pi}{3}$  for pairs of  $M_3$  particles (with head groups closer than tails) and an angle of 0 for pairs consisting of an  $M_1$  and an  $M_3$  particle.

We now turn to defining the interactions between surfactants and water. Clearly the head groups of  $M_1$  particles will be attracted to water over a broader range of angles than those of  $M_2$  and  $M_3$ . The repulsion between the tails of  $M_3$  particles and water will also extend over a wider range of angles than the other two particles. These varying affinities for water are summarised in figure 2, which shows the variation of the pairwise potential  $\phi$  for an amphiphile neighbouring a water particle over a range of orientation angles  $\theta$ . The  $M_2$  particle with its cylindrical geometry, feels an anti-symmetric repulsion as a function of  $\theta$ . Conversely, the  $M_3$  particles feel a broad ranged repulsion when their tails face water and only over a narrow range do they experience an attraction to water.

Figure 2: Pairwise potential  $\phi$  for a water and surfactant particle at neighbouring lattice sites. The potential varies as a function of the surfactant orientation  $\theta$  and takes on a different functional form for each of the three surfactant species. Note that in the model, the possible values of  $\theta$  are discretised, the continuous curves are indicative only.

At each time step, the potential energy field for each particle type is calculated using the interactions described above.

Particles then undergo stochastic transitions in pursuit of local energy minima. These transitions consist of translation by one lattice spacing and rotation (in the case of the anisotropic surfactant particles). Particle states are updated synchronously. As the particles relax into local minima the system as a whole tries to reach a state of global energy minimum analogous to the process of simulated annealing. The probability of a particle undergoing a transition is proportional to the value of the energy response function, evaluated for that transition (Ono and Ikegami, 2001):

$$f(\Delta\Phi) = \frac{\Delta\Phi}{e^{\beta\Delta\Phi} - 1} \quad (1)$$

$\Delta\Phi$  is the potential energy change of the transition and  $\beta = 1/T$  is the inverse temperature (we take Boltzmann's constant equal to unity). This function is designed to implement the basic character of a Boltzmann factor without the risk of the value diverging for large negative  $\Delta\Phi$  (transitions which are energy-reducing are not guaranteed to be accepted, as in a standard Monte Carlo algorithm). Simulations proceed by making use of this function to calculate transition probabilities. Particle states are then updated synchronously and randomly, biased by these probabilities.

## Results

We shall now examine the most important results from testing the model over a range of conditions. Note that all images shown here are sections taken from larger systems therefore the boundaries in the images do not wrap around in the periodic way that they do in the simulation. In all figures, depth of green corresponds to the concentration of oil particles, depth of blue corresponds to water concentration and depth of red to surfactant concentration.

### Phase Separation

We begin with a simple, characteristic situation: a 50:50 water-oil mixture. Since polar and organic solvents do not mix due to their differing capabilities for hydrogen bond formation, we would expect such a system to relax to a state of phase separation in which the surface tension (interfacial area or contour in 2D) between the two substances tends to a minimum. Figure 3 shows two snapshots from a simulation containing average densities of  $\rho_w = \rho_o = 7.5$  particles per lattice site, at a temperature of  $T = 0.8$ . We can see in figure 3(a) that the system separates into regions of almost pure water and oil in the early stages. Over time the average curvature of the interface between the two regions is persistently reduced. Close observation reveals the propagation of capillary waves across this interface (see animation at: <http://tinyurl.com/lipid-CAs>), a characteristic surface tension effect. Given sufficient time, the system will reach a state of a single straight interface separating the two phase regions. Since the relaxation time scales approximately exponentially with system size, one would have to

run the simulation for an extremely long time to reach this state. However we can already see this minimum energy configuration at smaller length scales within the system.

(a)

(b)

Figure 3: System configuration after a)  $t = 1 \times 10^4$  and b)  $t = 1 \times 10^6$  time steps for a binary mixture of water and oil particles.

### Surfactant-Water Mixtures

We now turn our focus to the behaviour of the surfactant particles in the presence of water. Experimental results from studies of real lipid systems lead us to expect structures such as micelles, bilayers and vesicles among others (Tresset, 2009). We also know that the appearance of such structures should depend on certain parameters such as the temperature and surfactant concentration.

**Micelles**  $M_1$  particles were designed to emulate detergent molecules with single alkyl chains. We represented this in the model by endowing them with a cone-like structure: a narrow tail region and broad head section. We would expect such particles to coalesce into micelles in the presence of water. In a micellar configuration, the contact between hydrocarbon tails and water is minimised whilst the energetic aspirations of the amphiphiles are also reasonably satisfied. We can see from figure 4 that the equilibrium structure exhibited by  $M_1$  particles is the micelle. The configuration

shown contains average densities of  $\rho_w = 12$  and  $\rho_{M_1} = 3$  particles per lattice site and had a temperature of  $T = 0.3$ . Increasing the surfactant concentration does not alter the micellar configuration, it simply causes a greater number and hence closer packing of micelles. Likewise decreasing the  $M_1$  concentration simply results in a smaller number of micelles as the surfactants have a lower probability of encountering one another as they perform random walks over the lattice. Given time they do begin to aggregate but the process is slow. Furthermore, if the temperature is high, the micelles cannot form because they require a certain threshold number of constituents before they can remain robust to thermal fluctuations. Micelles containing only a small number of particles are not robust to these perturbations and thus do not persist. Hence at low surfactant concentrations, micelles can only form at low temperatures where fluctuations are less frequent. Below the critical micelle concentration (CMC), micelles would be unable to form at any temperature. In our model the CMC is very low ( $\rho_{M_1C} < 1$  particle per lattice site) and we have not yet explored such low surfactant concentrations.

Figure 4: System configuration after  $t_f = 2 \times 10^5$  time steps for a binary mixture of water and  $M_1$  surfactant particles.

**Bilayers** We defined  $M_2$  particles as being similar to lipids with a cylindrical geometry. Their energetic requirements are satisfied if they align parallel with one another forming a straight bilayer. As was the case for  $M_1$  particles, this arrangement minimises the interfacial contact between hydrophobic tails and water while also satisfying the energetic preferences of the surfactants. Figure 5 shows a typical steady state of a water- $M_2$  mixture. It is clear that the self-assembly properties of this surfactant species are quite different from those of the  $M_1$  particle. Under identical conditions and concentrations,  $M_2$  particles assemble into bilayers, in contrast to the micelles formed by the  $M_1$  particle. If the concentration of  $M_2$  particles is very low, i.e.,  $\rho_{M_2} < 1$  particle per lattice site, below the critical bilayer concentration (CBC), micelles are formed rather than bilay-

ers. However they do not possess the central voids of the  $M_1$  micelles so they could also be described as small clusters. At these low concentrations, tuning the temperature to a critical value of  $T \approx 0.3$  allows a small number of bilayer sections to form but they are rapidly destroyed once the temperature reaches  $T = 0.4$ . This critical structure formation is analogous to the formation of micelles at low concentrations described in the previous section. Further investigations will reveal the nature of this transition region, within which well-defined structures form, but outside of which no such structures persist. As the concentration of  $M_2$  particles is increased above the CBC, the system becomes more densely packed with bilayers and the interconnectivity of the bilayers increases concomitantly.

Figure 5: System configuration after  $t_f = 2 \times 10^5$  time steps for a binary mixture of water and  $M_2$  surfactant particles.

**Bilayers and Reverse Micelles** The  $M_3$  surfactant possesses a broad tail region so it should be averse to micelle formation. Bilayers are also not the ideal structure since pairs of  $M_3$  particles would prefer to align with an angle of  $\frac{\pi}{3}$  between their long axes. In an organic solvent these particles would form reverse micelles, but it is not obvious what structures they would form in a polar solvent. Because  $M_3$  particles prefer not to form micelles or bilayers, they actually attempt to create an environment in which reverse micelle formation is possible. Figure 6 shows the equilibrium configuration of a mixture of water and  $M_3$  surfactants at the same concentration and temperature as the systems shown in figures 4 and 5. We can see that the system adopts a mixture of bilayers and clusters. On closer inspection, one finds that the clusters consist of amphiphiles forming a hexagonal phase. There are water particles at the centres of the reverse micelles due to the surfactant head groups being water soluble. In contrast the inter-micellar voids are just that, they are devoid of particles since they are apolar environments.

**Monolayers** Having evaluated the behaviour of water-oil and water-surfactant mixtures, we can now explore the equi-

(a)

(b)

Figure 6: a) System configuration after  $t_f = 2 \times 10^5$  time steps for a binary mixture of water and  $M_3$  surfactant particles. b) A closer view of the highlighted region from the upper figure showing a cluster of  $M_3$  particles which have assembled into a honeycomb structure allowing the formation of reverse micelles. Particles are drawn where there are 2 or more surfactants present in that position and orientation.

librium configurations of ternary solutions. The polar and organic solvents should again separate but now the surfactants can take up positions along the phase boundary in order to further minimise the total surface free energy. The surfactants should align themselves such that their polar heads are hydrated and their lyophilic tails mingle with the oil regions. Figure 7 displays such behaviour when we initialise a simulation with average densities of  $\rho_w = \rho_o = 7$  and  $\rho_{M_2} = 1$  and allow it to relax for  $t_f = 2 \times 10^5$  time steps at a temperature of  $T = 0.1$ . The surfactants rapidly line the oil-water interface and at low temperatures the system reaches a steady state where the oil islands become stationary and almost completely cease to merge or divide. At higher temperatures the system adopts a configuration identical in geometric character to that in figure 8(a). At this temperature,  $T = 0.4$  the system has more freedom to explore its mi-

crostates and hence over time the oil regions merge, grow in size and change shape in an effort to minimise their average curvature, analogous to the situation for the binary oil-water case. Fluctuations present in the initial conditions are gradually damped out. At these high temperatures, the process of potential energy minimisation struggles since the energy response function makes less of a distinction between transitions which are energy-reducing and those which incur an energy cost. So although there is phase separation and the surfactants assemble on the phase boundary, there are also surfactants spread thinly across the entire lattice. The bulk phase separation effects dominate here due to the large numbers of water and oil particles present and the high temperature. In contrast, at lower temperatures, the presence of the surfactants is more influential. This is visible in figure 7. Since  $M_2$  particles prefer to align parallel to one another, the oil-water interface takes on a slightly different appearance. It is composed of straight sections punctuated by sharp corners, typically turning through angles of  $\frac{\pi}{3}$ . Because the surfactant monolayer is rather inflexible at this low temperature, the system does not undergo any significant geometric changes once settled into the bicontinuous state shown in figure 7. We also explored situations in which the average oil densities were lower than the water densities. In these cases, the so-called microemulsion phase is exhibited, in which droplets of oil form, surrounded by surfactant boundaries. These droplets were seen to merge when they encountered one another.

Figure 7: System configuration after  $t_f = 2 \times 10^5$  time steps for a ternary mixture of water, oil and  $M_2$  surfactant particles.

### Melting and Re-freezing: Temperature-driven Hysteresis

In this section we shall present an example of a hysteretic effect in a ternary mixture. Comparison of figures 7 and 8(a), show that the temperature has a strong influence on the properties of the steady state structure. Higher temperatures allow a broader range of microscopic configurations

(a)

(b)

Figure 8: System configuration from a temperature-driven hysteresis experiment after a)  $t = 6 \times 10^5$  and b)  $t = 10 \times 10^5$  time steps, for a ternary mixture of water, oil and  $M_2$  surfactant particles. An animation of this experiment can be found at: <http://tinyurl.com/lipid-CAs>

to be explored per unit time. However these structures are much less stable than those which emerge at low temperatures. At high temperatures, what we see at large scales is an average of a large number of possible configurations which are being adopted and then eradicated again in rapid succession. Alas the randomising effects of thermal energy reign. Since the absence of these effects allows the system to maintain its configuration over longer periods, we would expect that cooling a warm system should freeze in the approximate configuration which prevailed before the cooling began. So if we were to take a stationary cool system, heat it, allow it to relax and then cool it again, the final steady state will be different from that which results from leaving the system at a constant low temperature. It is this effect that gives glasses their amorphous structure. The relaxation time required for the molecular constituents of glasses to settle into their equilibrium positions is so long that they have the appearance of a liquid which has had its molecular motion suspended. We expect that we can create a similar effect

with our model system. We performed just such an experiment in which we initialised a simulation with identical parameters to those of the system shown in figure 7. It was allowed to relax for  $2 \times 10^5$  time steps before the temperature was linearly raised from  $T = 0.1 \rightarrow 0.4$  over a period of  $2 \times 10^5$  time steps. The system was then left for another  $2 \times 10^5$  time steps. The configuration at this point is shown in figure 8(a). The temperature was then returned to  $T = 0.1$  linearly over  $2 \times 10^5$  time steps and the system was allowed to relax once more. The final state of the system at the end of this process is shown in figure 8(b). The most prominent feature of figure 8 is that the high temperature state has indeed been ‘frozen in’ or quenched. However the alignment preferences of the surfactants have caused the monolayer to become much more rigid. Furthermore, because the total interface length has been reduced by the heating process, there are now more than enough surfactants to line it. As the temperature was lowered and potential minimisation became a stronger imperative, free drifting surfactants were forced out of the water regions and were adsorbed onto the monolayer. Some surfactants then started to form bilayer sections since joining the monolayer incurred a greater energy cost than extending a bilayer into the water region. This experiment showed that the geometric features of the configuration are not a simple function of state. They depend not only on the current conditions, but also on the system’s history. When the system is initialised at a low temperature and remains at that temperature, it retains remnants of its initial configuration. If the same system is heated and then cooled again, the final configuration reflects the state of the system at previous times when the environment was different. Not all details are retained but the differences between figures 7 and 8(b) highlight the fact that current environmental conditions alone are not sufficient to define the configuration of the system.

## Conclusions

We have presented a model of amphiphile structure formation which is both simple and shows qualitative agreement with experiment. As a foundation we adopted the framework of the artificial chemistry model of Ono and Ikegami (2001). By re-formulating the way that surfactants are represented in the model, we have given it the ability to successfully simulate some of the most common phases of amphiphilic systems. We have shown its ability to reproduce micelles, bilayers, reverse micelles and monolayers. Other phases including microemulsions have also been simulated.

Armed with the knowledge that protocells spontaneously formed in the original model of Ono and Ikegami (2001), and having established the basic lipid phenomenology of this new model version, our future work will involve simulating protocellular chemical systems in which the cells can adopt different membrane curvatures depending on the distribution of lipids in their membranes. This lipid distribution will directly impact their robustness and hence their ‘fitness’

with respect to other cells within the system. For example, possessing a small number of  $M_1$  and  $M_3$  particles would enable a cell to have a membrane composed of straight sections (primarily  $M_2$  particles) punctuated by high curvature corners ( $M_1$  particles on the inner side of the bilayer and  $M_3$  particles on the outer side). Such a membrane would have a significantly lower surface tension than one constructed purely from  $M_2$  particles. The ability to exchange resources and wastes involved in the synthesis of new lipid particles controls how efficiently a protocell can repair damage to its membrane and also how easily it can grow and divide to form a pair of daughter cells. Therefore this ‘full’ version of the model might give clues as to how mechanisms for cellular lipid homeostasis might emerge spontaneously. Further selection pressure could be placed upon the protocells by relaxing the assumption of a uniform, stationary environment. We should also be able to simulate self-reproducing micelles (Bachmann et al., 1992), and complex reaction-diffusion systems (Szymanski et al., 2011).

## Abstract

We examine whether the process of technological innovation is an evolutionary process, in the sense that information that determines entities in the past is transmitted to entities in the future. We compare citation and PageRank statistics applied to data from the US patent record with data produced by certain non-evolutionary processes, captured by three classes of models that are driven respectively by what we term *random*, *preferential*, and *a priori* attachment. We make qualitative and quantitative comparisons of the cumulative citation curves produced by the patents and the three models, and find that random, *a priori*, and preferential attachment processes fail to explain certain significant patterns observed in the patent record—a result that corroborates the hypothesis that technological innovation is an evolutionary process.

## Is technological innovation evolutionary?

The advent of massive-scale systematic mining of aggregated social data, e.g., Michel et al. (2011), is transforming study of the evolution of science and technology. Earlier empirical study of the diffusion of innovations through social and economic markets (Rogers, 2003) can now be wedded with narrative theories the evolution of technology, e.g., Arthur (2009), and the analysis of innovation networks revealed in patent citation data (Jaffe and Trajtenberg, 2002). Interest in this topic rose sharply with the discovery that the growth and evolution of many kind of networks, including those consisting of citations among scientific papers (Redner, 1998; Barabasi and Albert, 1999; Lehmann et al., 2005) and patents (Valverde et al., 2007), exhibit power law behavior that can be modeled by various preferential attachment models. Here we take another look at this issue, and ask whether the characteristic dynamics of patent citations is well explained by three natural classes of models of the growth of patent citation networks.

There are a variety of reasons why those in artificial life might be interested in the evolution of technology. The process is driven by innovation, and understanding the role of innovation is essential to understand evolution, both in artificial life and in biology. If the technosphere—the set of all technological artifacts—displays a nontrivial form of evolu-

tion, it might itself be considered a sort living system, or a form of living technology (Bedau et al., 2010b,a).

The term “evolution” is usually used to describe the change of biological organisms over very long time periods, through a process that includes genetic variation of organisms from one generation to the next and natural selection based on survival of the fittest. This narrow biological view of evolution has been broadened to include long term changes in other non-biological systems; in recent literature one may find references to evolution of computer algorithms, evolutionary psychology, evolutionary history, cultural evolution, social evolution, sociocultural evolution, and technological evolution. But one may question the use of the term in all these contexts. A system may change over the long run, but when is that change properly termed evolution? Is there a well defined and empirically discernible difference between evolutionary change and non-evolutionary change?

Our view is that there is indeed a difference between evolutionary change and non-evolutionary change. For a system to evolve, it must be comprised of a population of entities, with a process for continual creation of new entities (the entities are analogs of biological organisms). The entities must be determined, at least in part, by some set of information (analog of an organism’s genome). And finally, there must be some process of selection taking place so that different entities are present to greater or lesser degree. We hold that such a system undergoes *evolutionary change* if and only if some of the information used in determining past entities persists and affects the determination of present and future entities (a form of heritability). If the present state of the population is substantially causally disconnected from all the determining information of previous populations, we would say that change is non-evolutionary. Biological evolution meets our definition of evolutionary change because the genetic information specifying present entities is copied from the genetic information from previous entities, perhaps modified by certain kinds of random mutations. Note that evolutionary change in the sense defined here covers both random genetic drift and darwinian evolution by natural se-

lection.

If the information determining a system's entities is measurable, the hypothesis that the system is evolving is testable through statistical analysis of those measurements. We consider the issue for technology, using citations in the patent record to examine whether or not technological change is evolutionary. In particular, we will consider the set of all technology that is represented by a patent granted by the United States Patent and Trademark Office (USPTO) during the period 1976-2010. Following our earlier work in this vein (Skusa and Bedau, 2002; Buchanan et al., 2011; Chalmers et al., 2010), we consider the set of patents as a changing population of entities, and we consider a patent to be "selected" whenever it is cited by another patent. When a new patent is issued, its immediate "ancestors" are considered to be the earlier patents that it cites, so citations are treated as the informational token indicating heritability. The most heavily cited patents are the key drivers of technological innovation.

Our previous work used various statistical measures based on citations to examine whether technological change is evolutionary. The citation-based statistics highlight various *a posteriori* narratives about superstar patents, *i.e.*, those that have especially high citation-based scores. Here we extend this analysis and examine other statistical indicators of a patent's persistence; specifically, we study second-order citations and PageRank, which can be viewed as depending on arbitrarily high-order past citations, and we examine whether these different statistical metrics alter the narratives of superstar patents. Finally, we measure the distance from the citation distributions observed in the patent record, to the characteristic citation distributions produced by three candidate generative models—a flat random attachment model, a preferential attachment model, and an *a priori* attachment model—and thus test the degree to which structure observed in the patent record is explained by our models. If the statistical character of data produced by a model is indistinguishable from the statistical character of the actual data, the actual data is well-explained by that model. We conclude that none of the three models considered effectively captures the structure found in the patent record.

## Statistics for quantifying evolution

In describing the citation dynamics of the patent record, we count citation events in which one patent cites another. A citation is a tuple: if  $p_1$  cites  $p_2$ , this first-order citation is the tuple  $(p_1, p_2)$ , and we say the relation  $c(p_1, p_2, t)$  holds, for  $p_1$  citing  $p_2$  at time  $t$ . (We sometimes assume an implicit existential quantifier over times, and simply speak of atemporal citation links between patents.) Previous work has examined the content of the citers of a patent  $p$  (Chalmers et al., 2010); in the present work, we focus on citation event tuples.

Let  $\overleftarrow{C}_1(p)$  be the set of first-order incoming citations of  $p$ :

$$\overleftarrow{C}_1(p) = \{(p', p) : \exists t, c(p', p, t)\}.$$

We can identify superstar patents by ranking all patents  $p$  according to their number of incoming citations,  $|\overleftarrow{C}_1(p)|$ . We can partition the set of incoming and outgoing citations into those received at some specific time  $t$ :

$$\overleftarrow{C}_1^t(p) = \{(p', p) : c(p', p, t)\}.$$

Generalizing, we let the *second-order citations* of a patent,  $\overleftarrow{C}_2(p)$ , be all the citation triples that end in  $p$ :

$$\overleftarrow{C}_2(p) = \{(p'', p', p) : \exists t, t', c(p'', p', t) \wedge c(p', p, t')\},$$

and partition a patent's second-order citations into those received at a specific time,  $t$ :

$$\overleftarrow{C}_2^t(p) = \{(p'', p', p) : \exists t' < t, c(p'', p', t') \wedge c(p', p, t)\}.$$

We regard a patent's *impact* on subsequent technological innovation as the cumulative weight of each citation event. For a counting function for an  $n^{\text{th}}$ -order citation,  $f^t(p_n, p_{n-1}, \dots, p_1, p)$ , we define a patent's  $n^{\text{th}}$ -order *impact*  $C_n^t(p)$  as the cumulative weight of citations to patent  $p$  up to time  $t$ :

$$C_n^t(p) = \sum_{t'=0}^{t'=t} \left( \sum_{(p_n, \dots, p_1) \in \overleftarrow{C}_n^{t'}(p)} f^t(p_n, \dots, p_1, p) \right). \quad (1)$$

The simplest version of a counting function is  $f^t(p_n, \dots, p_1, p) \equiv 1$ , in which case each citation in  $\overleftarrow{C}_n^t(p)$  is counted with equal weight.  $C_1^t(p)$  with this counting function is shown in the top of Figure 1. Buchanan et al. (2011) have shown that even this simple counting function reveals the main trends that remain prominent in the data after biases are removed.

We also iteratively calculate a patent's *PageRank*, which reflects the expected time that someone randomly surfing the patent citation network would spend visiting any given patent, as follows:

$$R_p^t(n) = (1 - d) + d \sum_{p' \in \overleftarrow{C}_1^t(p)} \left( \frac{R_{p'}^t(n-1)}{|\overleftarrow{C}_1^t(p)|} \right), \quad (2)$$

where  $n$  is the current iteration,  $d$  is a damping factor, and  $\overleftarrow{C}_1^t(p) = \{p' : c(p', p, t)\}$  and  $\overleftarrow{C}_1^t(p) = \{p' : c(p, p', t)\}$  are, respectively, the citers and citees of  $p$  up to time  $t$ . For all  $p$ , we let  $R_p^t(0) = 1$  and set  $d$  to 0.85, and perform 50 iterations—all as per convention in Page et al. (1999). A patent's PageRank changes over time, as the patent citation networks grows.

## Comparison of citations, second-order citations, and PageRank narratives

Earlier work operationalized high impact inventions as the most highly cited patents—termed patent “superstars.” Understanding superstar patents can help us understand what drives the evolution of technology in general. It turns out that superstar patents in the past few decades often involve PCR (the polymerase chain reaction that revolutionized contemporary biotechnology), inkjet printing, and stents (wire-mesh tubes that allow blocked coronary arteries to be repaired without open-heart surgery); see Buchanan et al. (2011) for details. The same methods also provide evidence that semiconductors, e-commerce, and wireless communication, for example, are also among the significant drivers of innovation during the last few decades (Chalmers et al., 2010). But the superstar status of PCR, ink-jet printing and stents remains a dominant pattern, so we illustrate our argument here by discussing those three key innovations.

Earlier work (Skusa and Bedau, 2002; Buchanan et al., 2011; Chalmers et al., 2010) compared citation counts of patents. Here, we extend the analysis to include two other natural statistics. We see in Figure 1 that the ten most cited patents appear among the top 100 when patents are ranked by second-order citations and PageRank, because more or less the same colored patents occur in all three plots. This shows that the PCR (red), inkjet printing (blue) and stents (green) narratives remain dominant when the patent record is analyzed by either citations, second-order citations, or PageRank. This rough correspondence between the three statistics tends to confirm that PCR, inkjet printing, and stents deservedly rank among the major technological innovations of the last thirty five years.

Nevertheless, the three different statistics do highlight different aspects of the patent record. For example, second-order citations correspond to the number of branches two levels down in the patent’s phylogenetic tree. The amount of green in the second-order citation plot shows the bushiness of the phylogenetic tree of the invention of stents—a conclusions confirmed by comparison of the phylogenetic trees of PCR, inkjet printing, and stents (data not shown). On the other hand, PageRank weights citations by the citer’s PageRank, so phylogenetic bushiness is insufficient by itself to boost PageRank. We see in the bottom of Figure 1 that stents (green) are significantly downplayed by PageRank, compared to PCR (red) and inkjet printing (blue). The observation that 25% of the top 20 patents ranked by second-order citation are about stents (green), while the top 100 patents include very few of the stent patents, might be connected with the earlier conclusion (Buchanan et al., 2011) that the stent patents are less “door-opening” than PCR and inkjet printing.

These qualitative conclusions are confirmed quantitatively by measuring the rank correlation between the patents when ranked by the three different statistics. The bottom

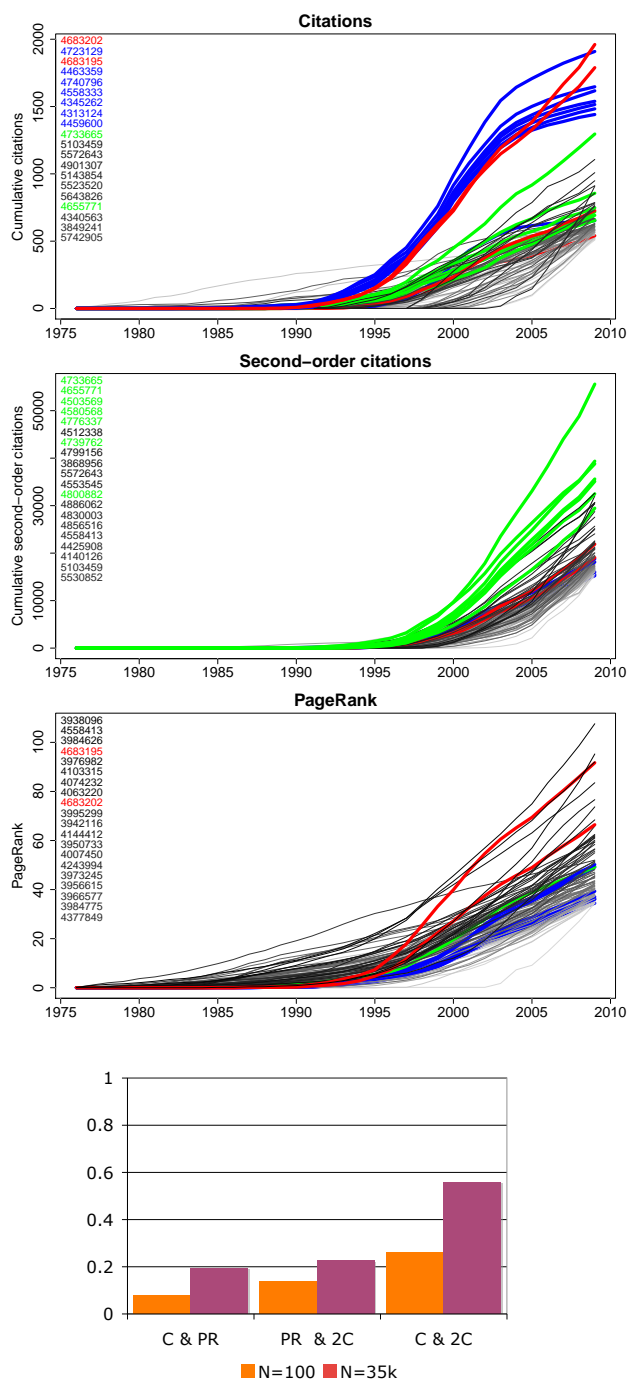

Figure 1: Top three panels: Dynamics in the patent record of cumulation first-order citations, cumulative second-order citations, and PageRank. Only the 100 highest-ranked patents are shown. Patents are color coded as follows: inkjet printing (blue), PCR (red), stents (green), other (gray). At the left are listed the patent numbers for the top twenty patents shown in each figure. Bottom: Rank correlations between the patents when ranked by citations and PageRank (C & PR), by PageRank and second-order citations (PR & 2C), and by citations and second-order citations (C & 2C), for the top 100 (orange) and the top 35k (purple) patents.

of Figure 1 reveals a significant difference between how the patents are ranked by the three statistics.

This conclusion can be generalized after examination of Figures 2 and 3. We can see in Figure 2 that most of the most heavily cited patents are also ranked highly by second-order citations and PageRank, because there is a lot of purple and brown at the top of the graphs. So, citations are highlighting something that is also picked up to some extent by second-order citations and PageRank. Similarly, we can see in Figure 3 that most of the patents with the highest PageRank are *not* also ranked highly by citations or second-order citations, because there is relatively little purple and brown at the top of the graphs. So, PageRank is highlighting something somewhat different than citations and second-order citations.

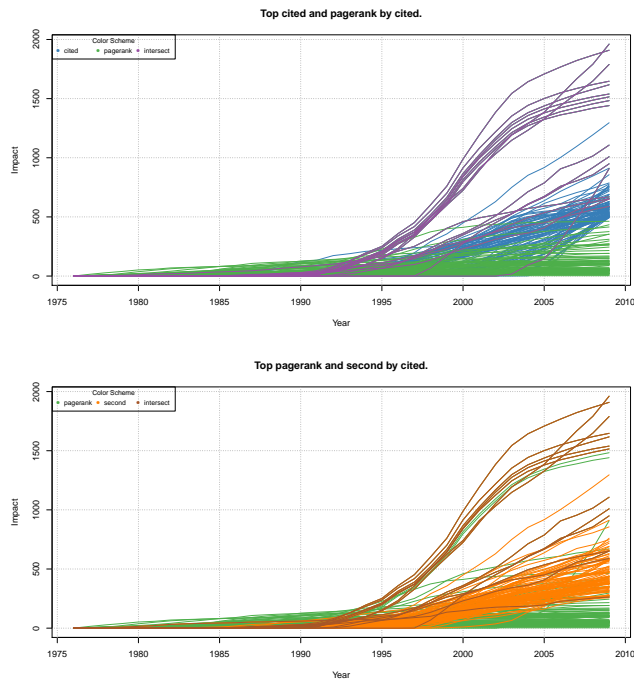

Figure 2: Above: First-order impact (cumulative citation) curves for the top 100 patents when ranked by citations or PageRank. Below: The same for the top 100 patents when ranked by PageRank or second-order citations. Patents are colored as follows: patents ranked among the top 100 only by citations (blue), those ranked among the top 100 only by PageRank (green), those ranked among the top 100 only by second-order citation (orange), those ranked among the top 100 by both citations and PageRank (purple), those ranked among the top by both PageRank and second-order citation (brown).

## Comparison with three models

We test whether a system is producing evolutionary change by comparing its citation network with the citation networks produced by various hypothetical non-evolutionary model systems, consisting of processes that generate citation networks, with different degrees of structure built into the processes. We test the likelihood of the hypotheses that the actual patent citation network was produced by a process embodied by those model systems, by comparing the statistical character of the citation networks produced by the model systems with that of the actual data. If, for a particular model system, the statistical character of the citation network were indistinguishable, we would say that the actual data is well-modeled by that model system.

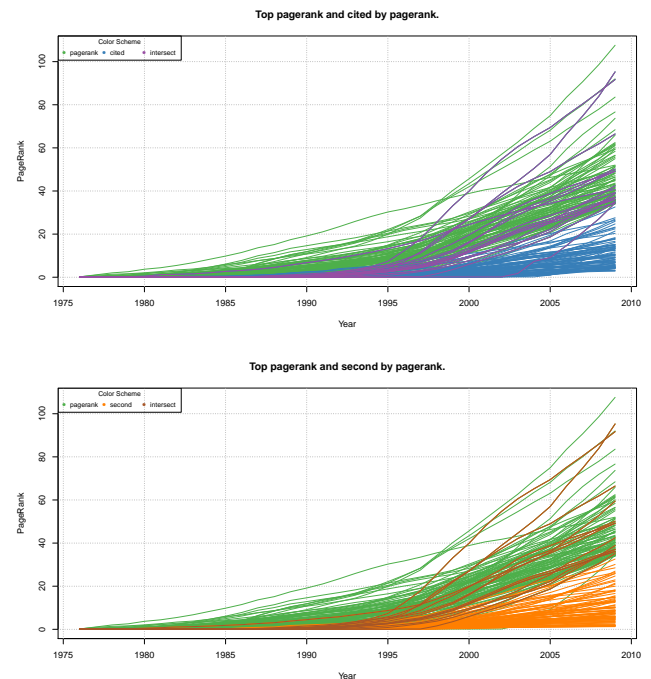

Figure 3: Above: First-order impact (cumulative citation) curves for the top 100 patents when ranked by citations or PageRank. Below: The same for the top 100 patents when ranked by citations or PageRank. Patents are colored as in Figure 2.

All the models work in the same basic fashion. Rather than the actual references made, each patent's citations are semi-randomly assigned, creating a new network of patent citations. The models differ in how citations are assigned, from completely randomly to significantly favoring certain patents as described below. All of these models are *non-evolutionary* because citation do not transfer information from one patent to another; information about a past patent is not inherited when a later patent cites it. Differing from the actual data, there is no lag between application and issue

Figure 4: Curves of first-order impact (cumulative citations) for the 100 most-cited patents produced by four different processes: Top: patents, including those about inkjet printing (blue), PCR (red), and stents (green). Upper Middle: flat neutral model. Lower Middle: preferential attachment model,  $PW = 2.0$ . Below: *a priori* attachment model (colors mirror US patents),  $APW = 0.9$ .

date in the models. An actual patent faces a delay of anywhere from two to four years on average between application and issuance, when other patents may begin to cite it. In the models, patents become eligible for citation immediately after their own citations have been reassigned. The models also differ from the actual data in allowing a patent to cite the same patent more than once. This eases implementation of models, and is not expected to significantly change their behavior.

### Random attachment model

In the random attachment model, the chance that a given patent has of being cited at a given time is equal to the chance that any other patent has of being cited at that time (Skusa and Bedau, 2002; Buchanan et al., 2011; Chalmers et al., 2010). Of course, the set of patents that available to be cited continually grows over time, and the number of incoming citations can fluctuate over time. More precisely, given a citing patent  $c$ , the chance of an earlier patent  $e$  receiving a citation is  $1/N$ , where  $N$  is the number of patents in our dataset issued before patent  $c$ . The random attachment model prevents the information determining past patents from having any effect on present or future patents that cite them.

### Preferential attachment model

We define a family of preferential attachment models,  $PA-k$ , where  $k$  is a parameter equal to the weight of preference parameter in the model. Here, we set  $k = 2.0$ , which results in the most frequently cited patents receiving approximately the same number of citations as most frequently cited real patents. More precisely, each patent,  $p'$ , is assigned a weight,  $w$ , which affects the chance of later patents citing it. That weight is a linear function of the number of citations received so far:

$$w' = b + kr \quad (3)$$

where  $b$  is the weight of a patent with no citations and  $r$  is the number of citations received to that point. Here,  $b$  was set to 1.0. A patent's chance of being cited is

$$\frac{w'_p}{\sum_{p \in M} w_p}$$

where  $M$  is the set of patents in our dataset issued prior to  $c$ . In the preferential attachment model, there is information about a patent that directly affects its probability of being cited—specifically, the number of citations it has already received. But that information is not inherited by the other patents that cite it.

### *A priori* attachment model

We define a family of *a priori* attachment models,  $AP-k$ , where  $k$  is a parameter equal to the weight of *a priori* attachments. These models choose which patents to cite by

sampling from a fixed “*a priori*” distribution of the relative “value” of each patent. Here, we choose this distribution to be given by the actual number of citations a patent has received by the end of 2010. We choose  $k = 0.9$ , because this leads to similar maximum numbers of citations received in the model and the actual data. Each patent’s weight for deciding citation assignments is given by

$$w' = a^k \quad (4)$$

where  $a$  is the patent’s *a priori* weight, in this case the number of citations received by 2011. Each patent’s chance of being cited is given by the ratio of its weight to the total weight, as in the preferential attachment model. As in the previous two models, in the preferential attachment model information used to determine a patent is not inherited by later patents that cite it.

### Comparison of scaled citation curves

We investigate whether the curves of cumulative citation counts of patents have a distribution of shapes that is significantly different from the distribution of shapes of cumulative citation curves produced by random attachment, preferential attachment, and *a priori* attachment.

The impact curves produced by random attachment, preferential attachment, and *a priori* attachment have distinctive characteristic shapes. The models produce curves with different characteristic shapes. Furthermore, none of the models produce curves very much like those displayed by patents. The different shapes are readily apparent in Figures 4 and 5.

Figure 4 compares the typical impact (cumulative citation) curves in the patent record with curves produced by three different null hypotheses. The 10 most cited patents fall into inventions: PCR (red), inkjet printing (blue), and stents (green). Note that the random attachment process produces curves of which the highest are over an order of magnitude smaller than the highest actual patent curves, even though both processes produce the same total number of citations. By contrast, we note that preferential and *a priori* attachment produce curves of about the same size as the patents; however, the similar sizes is a direct consequence of how we set the weights in those two modes. (Current work includes estimating the weights from the patent record itself.) Note that none of the colored patents appear in the random and preferential attachment curves; this is because we plot only the top 100 most cited patents, and the most cited patents in the random and preferential attachment processes are chosen from a uniform distribution, so the probability of a colored patent being in the top 100 is very low (about  $3 \times 10^{-6}$ ). By contrast, since we set a patent’s *a priori* probability of being cited by its actual citation count in 2010, the patents that are actually most cited—the colored patents—are expected to be the most cited patents produced by the *a priori* attachment model.

Figure 5: Curves of first-order impact (cumulative citations), scaled to the interval  $[0, 1]$ , for the 100 most cited patents (top, black), the 100 most cited patents produced by the random attachment model (green), preferential attachment (red) and *a priori* attachment (bottom, blue).

A good way to visualize the characteristic shape of the impact curves produced by the different processes is to mask their size differences by scaling them to the interval  $[0, 1]$ . Figure 5 shows that the shape of the curves of patents (black, top panel) is qualitatively different from the shape of the curves produced by random attachment (green, second panel), by preferential attachment (red, third panel), and by *a priori* attachment (blue, bottom panel). The random attachment curves (green) all increase at roughly the same expected linear rate. The preferential attachment curves (red) all have the same expected shape, which increases in lock-step with the number of patents being issued (Buchanan et al., 2011). The *a priori* attachment curves all increase linearly, starting immediately once a patent is issued. By comparison, the actual patents (black) display a wide variety of shapes, many of which are not found in the curves produced by the three models. This is strong evidence that the process producing the actual patent citation networks is not random attachment, preferential attachment, or *a priori* attachment.

The difference between these families of curves can be quantified using a measure of statistical distance between distributions, where each family corresponds to samples from the distribution describing that family. Statistical distance between univariate distributions is well measured by the Kolmogorov-Smirnov distance measure, which is simply the maximum difference between the cumulative distribution functions of the two distributions. The citation and Page rank curves, however, are not univariate. They are typically sampled each quarter of the year, which results in 132 measurements for each patent; *i.e.*, each curve is represented by a point in a 132-dimensional space, where each dimension represents the value of a statistic for one of the 132 quarters.

For distributions in higher dimensions, *i.e.*, multivariate distributions, distance measures are not quite so straightforward as in the univariate case. This is because in  $d$ -dimensional spaces the cumulative distribution depends on a choice of ordering of the coordinates, and there are  $2^d - 1$  possible orderings. One can define a distance as the supremum over all orderings, which is cumbersome to compute, or estimate based on a sample of orderings, or choose a particular ordering. We have used an `medcf` R package that computes a multivariate empirical cumulative distribution function for computation of a Kolmogorov-Smirnov distance.

Before constructing the cumulative distribution function, however, it is useful to reduce the dimension of the curves by fitting them to orthogonal polynomials. We used the first four Legendre polynomials, reducing each 132-value curve to a point in a five dimensional space. We then used `medcf` to construct the empirical cumulative distribution functions in the five dimensional space for each family of curves, and sampled that cdf eight values in each dimen-

sion ( $8^5 = 32,786$  samples), equally spaced over the range obtained by taking the minimum and maximum values for each coordinate. The estimated distance between two distributions is then the maximum value of the difference between the cdf samples for the two distributions, over all the sampled points. For example, the estimated Kolmogorov-Smirnov distance between two families of points in five dimensions, one produced by a Gaussian with mean zero and standard deviation one, and the other produces by a Gaussian with the same standard deviation, but a displaced mean, is about 0.4 if the two Gaussians are separated by two standard deviations.

Figure 6 shows the KS distances from the distribution of scaled cumulative citation curves in the patents for the curves produced by the *a priori* attachment model (blue), the preferential attachment model (red), and the random attachment model (green). The KS distance between the patents and both preferential and random attachment models quantitatively confirms what the eye can see in Figure 5: The shape of the curves is significantly different. At the same time, the KS distance is much less for the curves produced by *a priori* attachment, which also confirms what the eye tends to see in Figure 5.

Figure 6: KS distances between distributions of cumulative citation curves scaled to  $[0, 1]$ . Curves produced by the random, *a priori*, and preferential attachment models are compared with the curves derived from the patent record.

## Conclusions

The statistical exploration of the patent record supports two main conclusions about the process of technological innovation. First, the superstars of citations show up among the superstars of second-order citations, and also but to a lesser extent among the superstars of PageRank. The different statistics highlight somewhat different aspects of the patent record, but roughly the same stories come through with all

the statistics. In particular, PCR, inkjet printing, and stents are among the dominant innovations from all three perspectives. This implies that the superstar status of PCR, inkjet printing, and stents is not just a quirk of citation statistics; instead, those innovations are genuinely among the robust and dominant drivers of innovation in the past forty years.

Second, the shape of cumulative citation curves produced by the patents is significantly different from the shapes of the curves produced by random, *a priori*, and preferential attachment processes. This qualitative difference is corroborated by the significant KS distance between those same sets of curves. This implies that the process producing technological innovation is a fundamentally different from the processes produced by random, *a priori* and preferential attachment. This conclusion tends to be corroborated by earlier work that analyzed the size (rather than shape) of cumulative citation curves (Skusa and Bedau, 2002; Buchanan et al., 2011). Current work includes examining whether this conclusion is affected if the *a priori* and preferential attachment models are driven with an empirically estimated distribution of the probability of receiving a citation as a function of both the number of citations already accumulated and the age of the patent, in line with augmenting preferential attachment with “death” (Lehmann et al., 2005) or “aging” (Valverde et al., 2007).

The difference between the citation statistics found in the patent record and those produced by random, *a priori*, and preferential attachment processes suggests a further conclusion. Random, *a priori*, and preferential attachment are all non-evolutionary processes, because the information that determines the entities in the population is not inherited when those entities are cited in the future. By contrast, intuitively it seems that citations between patents *do* represent the propagation into the future of information about past technology, which implies that technological change is an evolutionary process. The difference between the statistical features of the data produced by the three classes of models and by the data found in the patent record corroborates the hypothesis that technological innovation is a genuinely evolutionary process.

## Abstract

We investigate the problem of optimal control of mutation by asexual self-replicating organisms represented by points in a metric space. We introduce the notion of a relatively monotonic fitness landscape and consider a generalisation of Fisher's geometric model of adaptation for such spaces. Using a Hamming space as a prime example, we derive the probability of adaptation as a function of reproduction parameters (e.g. mutation size or rate). Optimal control rules for the parameters are derived explicitly for some relatively monotonic landscapes, and then a general information-based heuristic is introduced. We then evaluate our theoretical control functions against optimal mutation functions evolved from a random population of functions using a meta genetic algorithm. Our experimental results show a close match between theory and experiment. We demonstrate this result both in artificial fitness landscapes, defined by a Hamming distance, and a natural landscape, where fitness is defined by a DNA-protein affinity. We discuss how a control of mutation rate could occur and evolve in natural organisms. We also outline future directions of this work.

## Introduction

The problem of optimal mutation rate has been studied for a long time (e.g. see Eiben et al., 1999; Ochoa, 2002; Falco et al., 2002; Cervantes and Stephens, 2006; Vafaei et al., 2010, for reviews). It relates directly to optimisation of genetic algorithms (GAs) in operations research and engineering problems (i.e. meta-heuristics). It is also related to some fundamental questions in evolutionary theory about the role of mutation in adaptation and biological mechanisms of DNA repair and mutation control.

As noted by Eiben et al. (1999), there are two trends in optimisation of parameters in GAs — optimal parameter setting and optimal parameter control. In the former, one looks for an optimal value of a parameter, which is then kept constant. Thus, Mühlenbein (1992) proposed mutation rate  $\mu = 1/l$ , where  $l$  is the length of sequences. The value  $1/l$ , as was pointed out by Ochoa et al. (1999), is related to the error threshold (Eigen et al., 1988). However, while mutation rate  $1/l$  can give satisfactory performance in some problems, the advantages of using a variable rate were becoming obvious to many researchers, leading to the problem

of optimal parameter control. In particular, Ackley (1987) suggested that mutation probability is analogous to temperature in simulated annealing, and should decrease with time. A gradual reduction of mutation rate was also proposed by Fogarty (1989). In a pioneering work, Yanagiya (1993) used Markov chain analysis of GAs to show that in any problem there exists a sequence of optimal mutation rates maximising the probability of obtaining global solution at each generation. A significant contribution to the field was made by Bäck (1993), who suggested that mutation rate  $\mu$  should depend on fitness values rather than time. Recently, Vafaei et al. (2010) used numerical methods to optimise a mutation operator based on the Markov chain model of GA by Nix and Vose (1992). The complexity of this model, however, restricts the application of this method to small spaces and populations. Thus, the precise form of the optimal mutation rate control, as well as question about the existence of such a control in the general case, remain open problems. These problems are extremely important not only for applications of GAs, but also for biology and evolutionary theory.

In biological systems, mutation, unlike natural selection, is an evolutionary process controlled, to a degree, by the organism. This control is primarily seen in highly refined DNA repair and replication machinery (e.g. Hakem, 2008). This ensures both that physical damage to genetic material is repaired and that, in the process of cell division, the newly synthesised copies of DNA faithfully reproduce the parental sequence. The result is that biological mutation rates are very low: DNA-based organism values typically being 1/300 per genome per replication, which, for genomes frequently in the range between  $10^6$  and  $10^{10}$  base-pairs, means extremely faithful repair and replication (Drake et al., 1998). Nonetheless, this observation also implies that biological mutation rates per base-pair are not minimised, since widely varying genome sizes imply very different per-base-pair rates. At a mechanistic level, some organisms do exist, such as the bacterium *Deinococcus radiodurans* with substantially more developed DNA repair or replication mechanisms than closely related species (Cox et al., 2010), implying that mutation rates elsewhere at least are not minimised.

Genetic variation also exists in mutation rates within species and in the way mutation rate changes with environment for a single genotype (Bjedov et al., 2003). Therefore, mutation rates and their variation are potentially subject to biological evolution themselves. Thus, while mutation rates are only a part of the biological evolutionary process, they merit examination independent of the vicissitudes of selection that are imposed on their products, which is what we address.

Our approach is based on theories of optimal control and information. However, we believe that the key to finding solutions that are relevant not only for engineering, but also for biology, is understanding the relation between a representation space, which is a discrete space of genotypes, and its (pre)-ordering by phenotypic fitness. Biology typically understands this relation via landscape metaphors, used in a variety of ways (e.g. classically adaptive landscapes of Wright, 1932, and ‘epistatic’ landscapes of Waddington, 1957). However, while the underlying elements, particular alleles of genes, are acknowledged as discrete, these landscapes have almost uniformly been theorised (and visualised) in continuous space following Fisher (1930). This is problematic when one comes to the mechanistic basis of biological evolution in discrete DNA mutations. Attempts are being made to reconcile such continuous models with individual DNA mutations (Orr, 2005). However, hitherto, these attempts have maintained a continuous view of the landscape space, in contrast to the reality of its discrete domain. Discrete views have typically been restricted to abstracted biological systems, such as aptamer (Knight et al., 2009) or RNA structure evolution, where landscape analogies can be dropped in favour of networks of sequences (Cowperthwaite and Meyers, 2007) which do not lend themselves to consideration of variable mutation sizes.

This work presents elements of a theory on optimisation of asexual reproduction by a mutation rate control together with its experimental evaluation. We introduce the notion of relatively and weakly monotonic fitness landscapes, and then develop the necessary machinery for Hamming spaces of sequences with arbitrary alphabets, which are particularly relevant in biology. Then we evolve mutation rate control functions using a meta genetic algorithm, and show that they closely match our theoretical predictions.

## Theory

Let  $\Omega$  be a countable set of all possible individuals  $\omega$  and  $f : \Omega \rightarrow \mathbb{R}$  be a fitness function. Assuming that fitness value  $x = f(\omega)$  is the only information available, let  $P(x_{s+1} | x_s)$  be the conditional probability of an offspring having fitness value  $x_{s+1}$  given that its parent had value  $x_s$  at generation (time)  $s$ . This Markov probability can be represented by a left stochastic matrix  $T$ , and if  $P(x_{s+1} | x_s)$  does not depend on  $s$  (i.e.  $T$  is stationary), then  $T^t$  defines a linear transformation of distribution  $p_s := P(x_s)$  of fitness values at time  $s$  into distribution  $p_{s+t} := P(x_{s+t})$  of fitness values

after  $t \geq 0$  generations:

$$p_{s+1} = T p_s = \sum_{x_s} P(x_{s+1} | x_s) P(x_s) \Rightarrow p_{s+t} = T^t p_s$$

We denote the expected fitness at generation  $s$  as

$$\mathbb{E}\{x_s\} := \sum_{x_s} x_s P(x_s)$$

If  $\mathbb{E}\{x_{s+t}\} \geq \mathbb{E}\{x_s\}$ , then individuals have adapted.

Suppose that the transition probability  $P_\mu(x_{s+1} | x_s)$  depends on a control parameter  $\mu$ , so that the Markov operator  $T_{\mu(x)}$  depends on the control function  $\mu(x)$ . Then the expected fitness  $\mathbb{E}_{\mu(x)}\{x_{s+t}\}$  also depends on  $\mu(x)$ . We interpret  $\mu(x)$  as a control function that parents use in reproduction to maximise expected fitness of their offspring based on the value of their own fitness. A particular example we shall consider here is when  $\mu$  is the mutation rate parameter.

If  $\Omega$  is the space  $\mathcal{H}_\alpha^l := \{1, \dots, \alpha\}^l$  of sequences of length  $l$  and  $\alpha$  letters, then by mutation we understand here a process of independently changing each letter in a parent sequence to any of the other  $\alpha - 1$  letters with probability  $\mu/(\alpha - 1)$ . This is point mutation, the simplest form of mutation defined by one parameter  $\mu$ , called the *mutation rate*.

The main result that we present in this paper is a mutation rate control function, which is approximately optimal for maximising expected fitness  $\mathbb{E}\{x_{s+t}\}$  in landscapes  $f(\omega)$  that are locally monotonic relative to the Hamming metric (this property will be defined later). This mutation rate function corresponds to the cumulative distribution function (CDF)  $P_e(x_r > x)$ ,  $r \in [s, s+t]$ , computed from empirical distribution  $P_e(x_r)$  of observed fitness values  $x_r$  over the period  $[s, s+t]$ :

$$\mu_e(x) = P_e(x_r > x) = \sum_{x_r > x} P_e(x_r) \quad (1)$$

We refer to this function as *informed mutation rate*, because it uses information communicated by random variable  $x$ . We first present the theory and assumptions behind this heuristic. Then we evaluate it against nearly optimal mutation functions, evolved using a meta genetic algorithm both for artificial and natural fitness landscapes.

## Problem Definition

Formally, an optimal control function (e.g. an optimal mutation rate function) is  $\bar{\mu}(x)$  achieving the following optimal (supremum) value:

$$\bar{x}(\lambda) := \sup_{\mu(x)} \{\mathbb{E}_{\mu(x)}\{x_{s+t}\} : t \leq \lambda\} \quad (2)$$

Here,  $\lambda$  represents a time constraint. Function (2) is non-decreasing and has the following inverse

$$\bar{x}^{-1}(v) := \inf_{\mu(x)} \{t \geq 0 : \mathbb{E}_{\mu(x)}\{x_{s+t}\} \geq v\} \quad (3)$$

Here,  $v$  is a constraint on the expected fitness at  $s + t$ . Thus,  $\bar{x}(\lambda)$  is the maximum adaptation in no more than  $\lambda$  generations;  $\bar{x}^{-1}(v)$  is the minimum (infimum) number of generations required to achieve adaptation  $v$ .

Optimal solutions  $\bar{\mu}(x)$ , defined by function (2), depend on the constraint  $t \leq \lambda$ . We are interested in solutions for  $\lambda$  that is large enough to achieve the maximum expected fitness  $\mathbb{E}\{x_{s+t}\} = \sup f(\omega)$ . This can be represented dually by function (3) with constraint  $v = \sup f(\omega)$ . We note that  $\bar{x}(\lambda) = \sup f(\omega)$ , if  $\lambda = \infty$ . However, generally  $\bar{x}^{-1}(v) \leq \infty$ , even if  $v = \sup f(\omega)$ . Thus, our objective is to derive one optimal control function  $\bar{\mu}(x)$  that can be used by each individual parent based on their fitness value throughout the entire ‘evolution’  $[s, s + t]$ . We note also that our formulation uses only the values of fitness, and therefore it extends to the case where  $f(\omega)$  is time-variable.

Specific expressions for  $P_\mu(x_{s+1} | x_s)$ , defining  $T_{\mu(x)}$ , can be learnt or derived analytically from the domain  $\Omega$  and its structure. The operator  $T_{\mu(x)}$  contains all information required to compute optimal values (2) and (3). Thus, in principle, one can find an optimal control function  $\bar{\mu}(x)$ , if the family of operators  $T_{\mu(x)}$  is known. For example, considering values  $x \geq v$  as absorbing states, one can use  $T_{\mu(x)}$  to compute the fundamental matrix of the corresponding absorbing Markov chain and minimise the expected convergence time to the absorbing states. Solving the complete optimisation problem, however, can be an intractable task. We shall formulate additional assumptions that will allow us to solve the problem for some important cases.

## Relatively Monotonic Landscapes

First, we shall make some assumptions about fitness  $f(\omega)$ , which on one hand will generalise and clarify the terms ‘smooth’ and ‘rugged’ fitness landscape, and on the other hand will allow us to obtain expressions for  $P_\mu(x_{s+1} | x_s)$ . In particular, we assume that there exists optimal individual  $\top \in \Omega$  (not necessarily unique) such that  $\sup f(\omega) = f(\top)$ . This is always true if  $\Omega$  is finite. Also, we shall equip  $\Omega$  with a metric  $d : \Omega \times \Omega \rightarrow [0, \infty)$ , so that similarity between  $a$  and  $b \in \Omega$  can be measured by  $d(a, b)$ , and assume that there is a relation between the metric  $d$  and the fitness function  $f$ . In particular, we define  $f$  to be monotonic relative to  $d$ .

**Definition 1** (Monotonic landscape). Let  $(\Omega, d)$  be a metric space, and let  $f : \Omega \rightarrow \mathbb{R}$  be a function with  $f(\top) = \sup f(\omega)$  for some  $\top \in \Omega$ . We say that  $f$  is *locally monotonic* (locally isomorphic) relative to metric  $d$  if for each  $\top$  there exists a ball  $B(\top, r) := \{\omega : d(\top, \omega) \leq r\} \neq \{\top\}$  such that for all  $a, b \in B(\top, r)$ :

$$-d(\top, a) \leq -d(\top, b) \implies (\iff) f(a) \leq f(b)$$

We say that  $f$  is *monotonic* (isomorphic) relative to  $d$  if  $B(\top, r) \equiv \Omega$ .

**Example 1** (Needle in a haystack). Let  $f(\omega)$  be defined as

$$f(\omega) = \begin{cases} 1 & \text{if } d(\top, \omega) = 0 \\ 0 & \text{otherwise} \end{cases}$$

This fitness landscape is often used in studies of GA performance. A two-valued landscape is used to derive error threshold and critical mutation rate, and elements  $\top$  are referred to as the *wild type*. Such  $f$  is locally monotonic relative to any metric, if for each  $\top \in \Omega$  there exists  $B(\top, r) \neq \{\top\}$  containing only one  $\top$ . Then conditions of the definition above are satisfied in all such  $B(\top, r) \subset \Omega$ . If  $\Omega$  has unique  $\top$ , then the conditions are satisfied for  $B(\top, \infty) = \Omega$ . In a two-valued landscape, optimal function  $\bar{\mu}(x)$  for any  $\lambda$  in (2) is defined by maximising the one-step transition probability  $P_\mu(x_{s+1} = 1 | x_s)$ .

**Example 2** (Negative distance to optimum). If  $f$  is isomorphic to  $d$ , then one can replace fitness  $f(\omega)$  by the negative distance  $-d(\top, \omega)$ . The number of values of such  $f$  is equal to the number of spheres  $S(\top, r) := \{\omega : d(\top, \omega) = r\}$ . One can easily show also that when  $f$  is isomorphic to  $d$ , then there is only one  $\top$  element:  $f(\top_1) = f(\top_2) \iff d(\top_2, \top_1) = d(\top_2, \top_2) = 0 \iff \top_1 = \top_2$ .

In monotonic landscapes, spheres  $S(\top, r)$  cannot contain individuals with different fitness. We can generalise this property by *weak* or  $\varepsilon$ -monotonicity, which requires that the variance of fitness within individuals of each sphere  $S(\top, r)$  is small or does not exceed some  $\varepsilon \geq 0$ . These assumptions allow us to replace fitness  $f(\omega)$  by negative distance  $-d(\top, \omega)$ , and derive expressions for transition probability  $P_\mu(x_{s+1} | x_s)$  using topological properties of  $(\Omega, d)$ .

Monotonicity of  $f$  depends on the choice of metric, and one can define different metrics on  $\Omega$ . Fitness landscapes that are at least weakly locally monotonic relative to the Hamming metric seem biologically plausible given the abundance of neutral mutations in nature and redundancy in the translation of DNA to protein sequences. Thus, we focus our attention on the case when  $\Omega$  is a Hamming space.

## Mutation and Adaptation in a Hamming Space

First, we outline a model of asexual reproduction in metric space  $(\Omega, d)$ , and define the relation of parameter  $\mu$  to topology on  $\Omega$ . This model is a generalisation of Fisher’s geometric model of adaptation in Euclidean space (Fisher, 1930). Then we shall specialise this to a Hamming space.

Let individual  $a$  be a parent of  $b$ , and let  $d(a, b) = r$ . We consider single-parent reproduction as a transition from parent  $a$  to a random point  $b$  on a sphere:  $b \in S(a, r)$ . We refer to  $r$  as a *radius of mutation*. Suppose that  $d(\top, a) = n$  and  $d(\top, b) = m$ . We are interested in the following probability:

$$\begin{aligned} P(m | n) &:= P(b \in S(\top, m) | a \in S(\top, n)) \\ &= \sum_{r=0}^l P(m | r, n) P(r | n) \end{aligned} \quad (4)$$

where the following notation was used

$$\begin{aligned} P(m \mid r, n) &:= P(b \in S(\top, m) \mid b \in S(a, r), a \in S(\top, n)) \\ P(r \mid n) &:= P(b \in S(a, r) \mid a \in S(\top, n)) \end{aligned}$$

If mutation radius  $r$  can be controlled via parameter  $\mu$ , then transition probability (4) depends on this parameter as well. Specific expressions for  $P_\mu(m \mid n)$  depend on the topology of  $\Omega$ . Let us consider the Hamming space.

Let  $\Omega$  be a space  $\mathcal{H}_\alpha^l := \{1, \dots, \alpha\}^l$  — a space of sequences of length  $l$  and  $\alpha$  letters and equipped with the Hamming metric  $d(a, b) := |\{i : a_i \neq b_i\}|$ . Then, given probability of mutation  $\mu(n) \in [0, 1]$  of each letter in the parent sequence  $a \in S(\top, n)$ , the probability that  $b \in S(a, r)$  is

$$P_\mu(r \mid n) = \binom{l}{r} \mu(n)^r (1 - \mu(n))^{l-r} \quad (5)$$

Probability  $P(m \mid r, n)$  is defined by the number of elements in the intersection of spheres  $S(\top, m)$  and  $S(a, r)$ :

$$P(m \mid r, n) = \frac{|S(\top, m) \cap S(a, r)|_{d(\top, a)=n}}{|S(a, r)|} \quad (6)$$

where cardinality of the intersection  $S(\top, m) \cap S(a, r)$  with condition  $d(\top, a) = n$  is computed as follows

$$\begin{aligned} |S(\top, m) \cap S(a, r)|_{d(\top, a)=n} = \\ \sum (\alpha - 2)^{r_0} \binom{n - r_-}{r_0} (\alpha - 1)^{r_+} \binom{l - n}{r_+} \binom{n}{r_-} \end{aligned} \quad (7)$$

where the triple summation runs over  $r_0, r_+$  and  $r_-$  satisfying  $r_+ \in [0, (r + m - n)/2]$ ,  $r_- \in [0, (n - |r - m|)/2]$ ,  $r_- - r_+ = n - \max\{r, m\}$  and  $r_0 + r_+ + r_- = \min\{r, m\}$ . These conditions are based on metric inequalities for  $r, m$  and  $n$  (e.g.  $|n - m| \leq r \leq n + m$ ). The number of sequences in  $S(a, r) \subset \mathcal{H}_\alpha^l$  is

$$|S(a, r)| = (\alpha - 1)^r \binom{l}{r} \quad (8)$$

Substituting equations (5)–(8) into (4) we obtain the expression for  $P_\mu(m \mid n)$  in Hamming space  $\mathcal{H}_\alpha^l$ .

### Analytical Solutions for Special Cases

If fitness  $f$  is isomorphic to the Hamming metric, then transition probabilities  $P_\mu(x_{s+1} \mid x_s)$  are completely defined by  $P_\mu(m \mid n)$  with  $x_{s+1} = -m$  and  $x_s = -n$ . The corresponding Markov operator  $T_{\mu(n)}$  is then an  $(l+1) \times (l+1)$  matrix completely defining the evolution on  $[s, s+t]$ ,  $t \leq \lambda$ , for a given mutation rate function  $\mu(n)$ , if all individuals are allowed to reproduce (with selection, one has to compose  $T_{\mu(n)}$  with a selection operator). For example, one can show that for  $\lambda = 1$ , the optimal mutation rate is a step function:

$$\mu_1(n) := \begin{cases} 0 & \text{if } n < l(1 - 1/\alpha) \\ \frac{1}{2} & \text{if } n = l(1 - 1/\alpha) \\ 1 & \text{otherwise} \end{cases}$$

Unfortunately, analytical or numerical solutions to optimisation problems (2) or (3) are not available or tractable for  $\lambda > 1$  and large  $l$ . However, analysis allows us to derive some main features of an optimal control function  $\bar{\mu}(n)$ .

Minimisation of the convergence time to state  $m = 0$  is related to maximisation of probability  $P_\mu(m = 0 \mid n)$ . Because  $r = n$  and  $|S(\top, 0) \cap S(a, n)|_{d(\top, a)=n} = 1$ , it has the following expression:

$$P_\mu(m = 0 \mid n) = (\alpha - 1)^{-n} \mu^n (1 - \mu)^{l-n} \quad (9)$$

Mutation rate maximising this probability is obtained by taking its derivative  $P'_\mu$  over  $\mu$  to zero, and together with condition  $P''_\mu \leq 0$ , this gives  $n - l\mu = 0$  or

$$\mu_2(n) = \frac{n}{l} \quad (10)$$

This linear mutation control function has very intuitive interpretation — if sequence  $a$  has  $n$  letters different from the optimal sequence  $\top$ , then substitute  $n$  letters in the offspring. One can show that the linear function (10) is optimal for two-valued fitness landscapes with one optimal sequence, such as the Needle in a Haystack discussed in Example 1. This is because expected fitness  $\mathbb{E}_{\mu(x)}\{x_{s+t}\}$  in this case is completely defined by probability (9). For other fitness landscapes that are monotonic relative to the Hamming metric, function (10) is an approximation of the optimal control, because it does not take into account transition probabilities  $P_\mu(m \neq 0 \mid n \neq 0)$  between other (transient) states, which may influence the expected time of convergence to  $m = 0$ . As a result, the convergence can be very poor in the initial stages of evolution on  $[s, s+t]$ .

Bäck (1993) derived probability  $P_\mu(m < n \mid n)$  of ‘success’ in the space  $\mathcal{H}_2^l$  of binary sequences, and then considered mutation rates  $\hat{\mu}$  maximising its value for each  $n = d(\top, \omega)$ . Our equations (4)–(8) allow us to perform such optimisation for arbitrary  $\alpha$ . This method makes significant improvement over the linear control for the speed of convergence in the initial stages of evolution on  $[s, s+t]$ . We note, however, that the resulting mutation controls do not achieve optimal values (2) or (3). One can show that maximisation of  $P_\mu(m < n \mid n)$  is equivalent to maximisation of conditional expectation  $\mathbb{E}\{u(m, n) \mid n\} = \sum_m u(m, n) P_\mu(m \mid n)$  of a two-valued utility function:  $u(m, n) = 1$  if  $m < n$ ; 0 otherwise. This function has only two values, and such optimisation of  $\mu(n)$  is not precise for fitness functions with more than two values. In fact, analysis using absorbing Markov chains shows that linear control (10) achieves shorter expected times of convergence into absorbing state  $m = 0$ .

### Empirically Informed Mutation Rate

Another approach to optimal control of parameters in evolutionary systems is based on theories of information and optimal coding. In brief, one can reformulate problems (2)

Figure 1: Cumulative distribution functions  $P_0(m < n)$  of distances to optimum under random distribution of sequences in  $\mathcal{H}_2^{30}$  and  $\mathcal{H}_4^{30}$ .

and (3) by replacing the time constraint  $t \leq \lambda$  with a constraint on information ‘distance’  $\mathbb{E}_{s+t}\{\ln(p_{s+t}/p_s)\} \leq \lambda$  of distribution  $p_{s+t} = T^t p_s$  from  $p_s$ . Although minimisation of information distance is not equivalent to minimisation of convergence time, this formulation has the advantage that the corresponding optimal values can be computed exactly and used to evaluate various control functions.

Our evaluation shows that adaptation  $\mathbb{E}\{x_{s+t}\} \geq v$  with the least information distance of  $p_{s+t}$  from  $p_s$  is achieved if mutation rate is identified with the CDF of the ‘least informed’ distribution  $P_0(x)$  of fitness values. In particular, assuming a uniform distribution  $P_0(\omega) = \alpha^{-l}$  of sequences in  $\mathcal{H}_\alpha^l$ , the distribution  $P_0(n) := P_0(\omega \in S(\top, n))$  of their distances from  $\top$  can be obtained by counting sequences in the spheres  $S(\top, n) \subset \mathcal{H}_\alpha^l$ . One can show also that this corresponds to binomial distribution with  $\mu = 1 - 1/\alpha$ :

$$P_0(n) = \binom{l}{n} \left(1 - \frac{1}{\alpha}\right)^n \left(\frac{1}{\alpha}\right)^{l-n} = \binom{l}{n} \frac{(\alpha - 1)^n}{\alpha^l}$$

In this case,  $\mathbb{E}\{n\} = l\mu = l(1 - 1/\alpha)$ . Under the minimal information distance assumption, the offspring will have very similar distribution, and the probability  $P_0(m < n)$  that an offspring is closer to  $\top$  is given by the CDF of  $P_0(n)$ , which can be used to control the mutation rate:

$$\mu_0(n) = P_0(m < n) = \sum_{m=0}^{n-1} P_0(m) \quad (11)$$

This mutation control function has the following interpretation — if sequence  $a$  has  $n$  letters different from the optimal sequence  $\top$ , then substitute each letter in the offspring with the ‘least informed’ probability of improvement relative to the current value  $n = d(\top, a)$ . Figure 1 shows  $P_0(m < n)$  for  $\mathcal{H}_2^{30}$  and  $\mathcal{H}_4^{30}$ . We note that minimisation of information distance of  $p_{s+t}$  from  $p_s := P_0$  corresponds to maximisation of entropy of  $p_{s+t}$ , but adaptation  $\mathbb{E}\{x_{s+t}\} \geq \mathbb{E}\{x_s\}$

leads to increasing the distance and decreasing the entropy (i.e. slow ‘cooling’ as in simulated annealing).

In the next section, we present nearly optimal mutation rate functions, obtained experimentally, and find that they correspond to CDFs of distributions that are skewed towards the optimum compared to the CDFs of the least informed distributions  $P_0$  (i.e. skewed to the left compared to those used in Figure 1). This can be explained by the fact that the offspring sequences do not have a uniform distribution in  $\mathcal{H}_\alpha^l$  during long intervals  $[s, s + t]$  due to adaptation  $\mathbb{E}_{\mu(n)}\{m\} \leq \mathbb{E}\{n\} = l(1 - 1/\alpha)$ . Therefore, the probabilities of improvement relative to the current fitness are higher than  $P_0(m < n)$ , and they can be approximated by empirical functions  $P_e(m < n)$ , observed during  $[s, s + t]$ . Thus, we refer to such a control as ‘informed’.

Finally, we note that if fitness is monotonic relative to the Hamming metric, then function  $P_e(m < n)$  can be replaced by function  $P_e(x_r > x)$  for fitness values. We conjecture that the corresponding control (1) of mutation rate should achieve good performance also in landscapes that are only weakly or  $\varepsilon$ -monotonic. Our experiments with an aptamer landscape (Rowe et al., 2010) support this hypothesis.

## Evolving Optimal Mutation Rates

To evaluate our theoretically derived mutation control functions, we have evolved such functions independently using a meta-genetic algorithm (Meta-GA). Populations of the Meta-GA comprised individual functions  $\mu(x)$ , which were then used to control mutation rates of another GA, referred to as Inner-GA. We first give some details about the Inner- and Meta-GAs, and then describe results of the experiments.

### Inner-GA

The Inner-GA is a simple generational genetic algorithm that uses no selection and no recombination. Each genotype in the Inner-GA is a sequence  $\omega \in \mathcal{H}_\alpha^l$ , and we used populations of 100 individuals. The initial population had equal numbers of individuals at each fitness value, and all runs within the same Meta-GA generation were seeded with the same initial population. Individuals were evolved by the Inner-GA for  $t = 500$  generations using simple mutation. The objective was to maximise a fixed fitness function  $f(\omega)$ . Here, we report results of the following three experiments:

1.  $\mathcal{H}_2^{30}$  (i.e.  $\alpha = 2, l = 30$ ) and fitness  $f(\omega) = -d(\top, \omega)$ , where  $d$  is Hamming metric.
2.  $\mathcal{H}_4^{10}$  (i.e.  $\alpha = 4, l = 10$ ) and fitness  $f(\omega) = -d(\top, \omega)$ , where  $d$  is Hamming metric.
3.  $\mathcal{H}_4^{10}$  (i.e.  $\alpha = 4, l = 10$ ) and fitness  $f(\omega)$  defined by a complete DNA-protein affinity landscape for 10-base-pair sequences (Rowe et al., 2010), which we refer to as the aptamer landscape.

Figure 2: Average of evolved mutation functions  $\mu_e(n)$  and CDF  $P_e(m < n)$  for fitness  $f(\omega) = -d(\top, \omega)$  in  $\mathcal{H}_2^{30}$ .

Figure 3: Average of evolved mutation functions  $\mu_e(n)$  and CDF  $P_e(m < n)$  for fitness  $f(\omega) = -d(\top, \omega)$  in  $\mathcal{H}_4^{10}$ .

### Meta-GA

The Meta-GA is a simple generational genetic algorithm that uses tournament selection (a good choice when little is known or assumed about the structure of the landscape). Each genotype in the Meta-GA is a mutation rate function  $\mu(x)$ , which is a sequence of  $l + 1$  real values  $\mu \in [0, 1]$  representing per-locus probabilities of mutation. We used populations of 100 individual functions, which were initialised to  $\mu(x) = 0$ .

The Meta-GA evolved functions  $\mu_e(x)$  for  $t = 5 \cdot 10^5$  generations to maximise the average fitness in the final generation of the Inner-GA. The Meta-GA used the following selection, recombination and mutation:

- Randomly select three individuals from the population and replace the least fit of these with a mutated crossover of the other two; repeat until all individuals from the population have been selected.
- Crossover (recombination) uses a single cut point chosen randomly (excluding the possibility of being at either end, so that there are no clones).
- Mutation adds a uniform-random number  $\Delta\mu \in [-.1, .1]$  to one randomly selected value  $\mu$  (mutation rate) on the individual (mutation rate function), but then bounds that value to be within  $[0, 1]$ .

The Meta-GA returned the fittest mutation rate function  $\mu_e(x)$ . In addition, we recorded empirical frequencies  $P_e(x)$  of fitness values  $x = f(\omega)$ , observed during running the Inner-GA for  $t$  generations on the relevant landscape and using that mutation rate function. We note that empirical frequencies  $P_e(x)$  counted only the number of phenotypic mutations (i.e. genetic mutations that result in a change in fitness). Empirical frequencies  $P_e(x)$  were then used to compute the cumulative distribution functions  $P_e(x_r > x)$ , which we then compared to the evolved  $\mu_e(x)$ .

Figure 4: Average of evolved mutation functions  $\mu_e(x)$  and CDF  $P_e(x_r > x)$  for fitness  $f(\omega) = x$  from the aptamer landscape (Rowe et al., 2010) in  $\mathcal{H}_4^{10}$ .

### Experimental Results

We performed multiple runs of each experiment collecting multiple versions of evolved mutation control functions  $\mu_e(x)$  and cumulative distribution functions  $P_e(x_r > x)$  of observed fitness values. Figures 2, 3 and 4 show the average of these functions from 20 runs together with standard deviations. Figures 2 and 3 are for the experiments in  $\mathcal{H}_2^{30}$  and  $\mathcal{H}_4^{10}$  respectively, and with fitness  $f(\omega)$  defined by the negative Hamming distance  $-d(\top, \omega)$  to a fixed optimum  $\top$ . Figure 4 is for the experiment in  $\mathcal{H}_4^{10}$ , but with fitness  $f(\omega)$  defined by the complete aptamer landscape from (Rowe et al., 2010). The evolved functions  $\mu_e(x)$  are approximated fairly by the cumulative distribution functions  $P_e(x_r > x)$ , supporting heuristic (1). The mismatch in the areas of low fitness can be explained by slower convergence of functions  $\mu_e(x)$  in this part of the space  $\mathcal{H}_\alpha^l$  due to limited exploration of it by populations of 100 individuals in the Inner-GA, which are small relative to  $|\mathcal{H}_\alpha^l| = \alpha^l$ .

## Discussion

In this work, we have made some progress towards understanding optimal control of mutation rate, and some general principles can be formulated. It appears that choice of a representation space and its topology is crucial, as it defines the monotonic property of a fitness landscape. Our analysis was performed for a Hamming space, but the ideas can be extended to other spaces, such as a space of variable or infinite sequences with  $p$ -adic metric. If the right representation has been found, then specific formulae can be derived using geometric analysis in the representation space. These principles can also be extended to sexual reproduction and control of recombination. Our analysis and experiments suggest that an optimal control of mutation rate is based on statistical information about the distribution of fitness values.

The existence of optimal mutation rates that vary depending upon an individual's fitness raises a number of questions about the existence and control of variable mutation rates in biological organisms. For mutation rate control to have evolved in nature, a first prerequisite is that biological mutation rates can vary and are not simply minimised. There is ample evidence that mutation rates do vary in nature, between distantly (Drake et al., 1998) and closely-related (Matic et al., 1997) organisms, between regions of genomes (Lang and Murray, 2008) and even within an organism in stressful versus benign environments (Bjedov et al., 2003). However, the question of whether there may be an adaptive trait, allowing an individual organism to affect the number of mutations between itself and its offspring, dependent upon environmental cues, remains an open question. This would be an example of 'higher-order' selection, that is selection not on the immediate fitness of an individual, but on its ability to produce fitter descendants, potentially many generations later. Such higher order effects have always been questioned in biology, since they might be expected, in real populations, to be swamped by direct selective effects (Pigliucci, 2008). However, discussion has intensified recently over the concepts of 'robustness' and 'evolvability' (Masel and Trotter, 2010). These are higher order effects of somewhat unclear definition; the latter potentially relates directly to the control of mutation rate considered here. Very recent results from experimental evolution of microbial populations show that higher order evolvability effects can indeed play an important part in the evolution of real biological populations (Woods et al., 2011). However, in mechanistic terms, only the gross evolution of mutation rate itself (rather than mutation rate control) in 'mutator' strains has been identified in such experiments (Arjan et al., 1999).

If one moves from complete organisms to viruses and *in silico* quasi-biological evolution, there is more work on optimal mutation rates and their evolution. Optimal mutation rates can be identified (Kamp et al., 2002), relating to the concept of an 'error threshold' (Ochoa et al., 1999) the mutation rate at which selection can no longer be sufficient to

balance the deleterious effects of mutation (Biebricher and Eigen, 2005). However, Clune et al. (2008) used digital organisms to show that natural selection does not always effectively evolve optimal mutation rates for adaptation in the long-term, and this fact is particularly apparent when evolution occurs on a rugged fitness landscape. There is evidence that, in nature, epistasis is widespread (e.g. Costanzo et al., 2010), leading to rugged fitness landscapes. This potentially reduces the biological relevance of work, such as ours, with simple fitness functions. Nonetheless, even in rugged landscapes, biological evolution is, empirically, able to occur via locally monotonic accessible paths (Poelwijk et al., 2007), and we find a good agreement between the evolved and theoretical functions, even for a fitness landscape known to be rugged (e.g. Fig. 4 in Rowe et al., 2010). Similarly, temporal variation in fitness landscapes has been highlighted as biologically important (Costanzo et al., 2010), which, while it calls into question the biological relevance of optimal mutation rates in static landscapes, leads back to the potential biological importance of mutation rate variation in response to environmental cues (Stich et al., 2010).

Finally, we observe that understanding of evolution and dynamical systems, such as populations of organisms, may be facilitated by theories of information and information dynamics. In particular, optimisation problems, defined by functions (2) and (3), can be reformulated by replacing time with an information distance between probability distributions. Analytical solutions for such problems can be obtained (e.g. Belavkin, 2010), providing an alternative way to evaluate control functions. Although we do not report such evaluation here, we have observed that these information-theoretic optimal values are achieved when the mutation rate corresponds to a CDF of the 'least informed' distribution of fitness values. Understanding this relation between mutation rate control and information, along with its biological relevance, are some of the directions of our future work.

## Abstract

One of the practical challenges facing the creation of self-assembling systems is being able to exploit a limited set of fixed components and their bonding mechanisms. Staging addresses this challenge by dividing the self-assembly process into time intervals, and encodes the construction of a target structure in the staging algorithm itself and not exclusively into the design of components. Previous staging strategies do not consider the interplay between component physical features (morphological information). In this work we use morphological information to stage the self-assembly process, with the benefit of reducing assembly errors and leveraging bonding mechanism with rotational properties. Four experiments are presented, which use heterogeneous, passive, mechanical components that are fabricated using rapid prototyping. Two orbital shaking environments are used to provide energy to the components, and to investigate the role of morphological information with component movement in either two or three spatial dimensions. The experiments demonstrate, as proof-of-concept, that staging enables the self-assembly of more complex morphologies not otherwise possible.

## Introduction

Comprehending the principles of self-assembly has been described as one of the important aspects to understanding life (Ingber, 1998). Self-assembly is also considered to being an *enabling technology* for the creation of artificial systems (Pelesko, 2007). Constructing systems with natural characteristics (e.g. self-assembly, self-repair, and parallel construction) as a form of emergent engineering requires an understanding of the interplay between programmability/controllability and self-organisation (Doursat, 2008).

One important challenge when creating artificial self-assembling systems is caused by the use of components that lack the plasticity of biological cells. Using components that cannot differentiate results in self-assembly being constrained to a limited set of fixed components and their bonding mechanisms (Demaine et al., 2008). One strategy to address this challenge is to divide the self-assembly process into stages, referred to as *staged* or *hierarchical* self-assembly. Demaine et al. (2008) formalised the method of staging where components can be added to, or removed from, an environment at various time intervals.

Demaine et al. (2008) demonstrated the benefits of staging theoretically using abstract tiles, where staging the self-assembly process was based on the temporal aspects of conducting laboratory experiments. In contrast, we use physical components, and propose using morphological information as the dividing basis to staging the self-assembly process, inspired by biological development. Here we consider how physical features in a set of heterogeneous, passive, mechanical components can be exploited to reduce potential assembly errors, leverage rotational bonding mechanisms, and create structures with symmetrical/asymmetrical features. Our staging strategy is consistent with the definition of self-assembly (Whitesides and Gryzbowski, 2002), as a process involving components that can be controlled through their proper design and their environment, and where components can adjust their relative positions.

Staged self-assembly provides the advantage of encoding the construction of a target structure in the staging algorithm itself and not exclusively into the design of the components. For example, a staging algorithm can be used to reintroduce previously used components and bonding mechanisms at later time intervals, prevent the formation of holes, and create more complex morphologies that may not be otherwise possible due to shape conflicts between components.

The following section provides background material to which our staging strategy is built upon. Next, an overview of our approach is provided, including a theoretical model and physical description of the components and environments used. Four experiments follow that demonstrate the creation of self-assembled structures, from a set of components that are divided into two time intervals based on their physical features. Components are fabricated using rapid prototyping, and are placed in one of two orbital shaking environments (on a tray surface or in a jar of fluid). These two environments are used to demonstrate the role of morphological information in terms of component movement spatially in two and three dimensions (2D and 3D). We conclude by summarising how this work provides proof-of-concept evidence for staging the self-assembly process using morphological information.

## Background

Biological development utilises explicit stages in its provision of a solution to the construction of multicellular organisms (Wolpert, 1998). The explicit stages in biological development are often irreversible, and cannot be repeated at later stages, such as invagination, gastrulation, and the formation of a body plan. Staged development in nature allows for the creation of more complex phenotypes, which otherwise would not be possible (Wolpert, 1998).

A challenge towards the creation of self-assembling systems is the use of fixed components in contrast to components that can differentiate and communicate (e.g. cells in biological organisms). *DNA nanotechnology* is one example of an application area using fixed components, such as DNA tiles (using interwoven double-stranded DNA to create the body of a tile, and single DNA strands extending from the edges of a tile's body; Winfree et al., 1998). The staged Tile Assembly Model (sTAM) addresses this challenge by incorporating the temporal aspects of conducting laboratory experiments, using DNA tiles for example, into the self-assembly process (Demaine et al., 2008).

The sTAM is an extension to the abstract Tile Assembly Model (aTAM; Winfree, 1998). The aTAM was developed to provide a theoretical framework to investigate the assembly of square tiles (based on DNA tiles) in a square lattice environment. A tile type is defined by the bonding domains on the North, West, South, and East edges of a tile. At least one seed tile must be specified to start the self-assembly process. Tiles cannot be rotated or reflected. There cannot be more than one tile type that can be used at an assembly location in the growing structure. Tile types are in infinite supply, of equal concentration, in the model. All tiles are added to the same environment, *one-pot-mixture*. Tiles can only bond together if the interactions between them meet or exceed the *temperature* parameter. As a result, temperature dictates *co-operative bonding*. The seed tile is first placed in the environment, and additional tiles are added one at a time if the bonding constraints are satisfied.

The sTAM extends the aTAM by dividing the self-assembly process into time intervals. Components can be added to, or removed from, as set of environments, mirroring the laboratory operations of adding/filtering DNA-based components to solutions that can be mixed together. The sTAM has been used to investigate the algorithmic construction of structures, such as a fully connected  $n \times n$  square ( $n \in \mathbb{N}$ ). The construction of a square is problematic, as assembling tiles must be coordinated to prevent the occurrence of holes. The sTAM has shown an algorithmic efficiency with minimal tile sets and bonding mechanisms (not requiring co-operative bonding, at temperature one) in the construction of such structures. This efficiency is due to staging, and is an advantage over the aTAM itself that relies on co-operative bonding (Rothmund and Winfree, 2000), or other extensions to the aTAM that use either changes in temperature

Figure 1: Three-level approach to self-assembly design.

(Kao and Schweller, 2006) or by varying the concentration of tiles (Adleman et al., 2001; Doty, 2009).

*Situated development* is another method investigating staged construction, where artificial evolution was used to evolve the assembly plan of a structure (Rieffel and Pollack, 2005). Based on rapid prototyping, assembly plans were evolved using *permanent* and *temporary* components which were “dropped” in an environment. Temporary components act as scaffolding and can be removed (representing how support material can be removed in rapid prototyping).

In contrast to Demaine et al. (2008) and Rieffel and Pollack (2005), physical examples of staged self-assembly include Wu et al. (2002) where templates were used to self-assemble spherical beads into substructures with specific patterns (e.g. linear, triangular, and hexagonal shapes). As well, He et al. (2008) used three-point start motif tiles to self-assemble tetrahedrons, dodecahedrons, and buckyballs by controlling the motif length and concentration of tiles in a two-step process. Despite this work, there is little (if any) literature that describes the use of morphological information to stage the self-assembly process.

## Staging and the Three-Level Approach

The three-level approach provides a high-level description to designing self-assembling systems via physically encoded information (Bhalla et al., 2010). The three levels include: (1) definition of rule set, (2) virtual execution of rule set, and (3) physical realisation of rule set (Fig. 1). Here we extend the three-level approach to incorporate our staging strategy. At level one, a new self-assembly rule is introduced to specify which components are present at a particular time interval. To accommodate this new rule, an extension to a self-assembly model based on the aTAM is provided at level two. Finally, physical features of components that are exploited in our staging experiments is described at level three.

### Level One: Definition of Rule Set

A system is described by three categories of self-assembly rules, *component*, *environment*, and *system*, which are in the context of component movement spatially in 2D or 3D.

Component rules specify shape and information. Conceptually similar to DNA tiles, components are either squares

Figure 2: 3D component spatial relationship, and an example of information orientation on a 3D component's face.

(2D) or cubes (3D). Each edge/face of a component serves as an information location (Fig. 2), in either a four-point (Top-Left-Bottom-Right) or six-point arrangement (Top-Left-Bottom-Right-Front-Back). Information is represented by a capital letter (A to H for 2D components, and I to T for 3D components). A subscript (1 to 4) is used with each capital letter (e.g.  $N_4$ ) to indicate orientation on a 3D component's face. The dash symbol (—) represents a neutral site (where no assembly information is present). The spatial relationship of a component's information defines its type.

Environment rules specify environmental conditions such as temperature ( $\phi$ ) and *boundary* constraints. An assembly protocol must at least meet the temperature for assembly bonds to occur. The boundary confines components to the environment. Components are permitted to translate and rotate in 2D and 3D systems. In addition, components have rotational information and can be reflected in 3D systems.

System rules specify component type frequency in each time interval ( $\psi$ ), and two interaction rules (*fits* and *breaks*). Time intervals indicate when components are added to a single environment (e.g.  $\psi_0$ ; using a subscript 0 to n, where  $n \in \mathbb{N}$  and 0 indicates the start of the self-assembly process). If two complementary pieces of information come into contact, (e.g. A fits B), it will cause them to assemble. This rule type is commutative (e.g. if A fits B, then B fits A). Furthermore, fits rules encapsulate component-to-component rotational interactions in 3D systems. A subscript (360, 180, and 90) is used to represent if the faces of complementary 3D components can fit together in four, two, or in one way respectively (e.g. M fits<sub>180</sub> N). If two assembled pieces of information experience at least a temperature of two ( $\phi_2$ ), then their assembly breaks. The system rules in conjunction with their physical counterparts is provided at the end of this section, *Level Three: Physical Realisation of Rule Set*.

## Level Two: Virtual Execution of Rule Set

At level two, a self-assembly rule set is mapped to an abstract tile model for computational efficient evaluation, and is used to determine if physical evaluation of a self-assembly rule set is applicable at level three. We extend the concurrent Tile Assembly Model (cTAM; Bhalla et al., 2010) to incorporate staging. In contrast to the aTAM, the cTAM is better suited to the type of self-assembling systems used here by al-

Figure 3: 2DscTAM example, and 2D assembly violations.

lowing multiple substructures to self-assemble concurrently, not using seed tiles, permitting more than one tile type to be used at an assembly location, and requiring all tiles to be in the same one-pot-mixture environment. The extended cTAM is referred to as the 2D and 3D staged concurrent Tile Assembly Model (2DscTAM and 3DscTAM). Components are permitted to translate and rotate in both the 2DscTAM and the 3DscTAM, but only be reflected in the 3DscTAM.

The input into the 2DscTAM and the 3DscTAM is the number of time intervals, and the multiset of components in each interval (type and frequency). At the start of each time interval, the components corresponding to the current time interval are added to the environment (Fig. 3). A single assembly operation is applied during a time interval, initialised by selecting a single tile/substructure with an open assembly location at random. If no other tile/substructure has an open complementary information location, then the location on the first tile/substructure is labelled *unmatchable*. If there are tiles/substructures with open complementary information locations, all those tiles/substructures are put in an *assembly candidate list*. From the assembly candidate list, tiles/substructures are selected at random until a tile/substructure can be added. If no such tile/substructure can be added, due to an *assembly violation* (Fig. 3), then the location is labelled *unmatchable*. If a tile/substructure can be added, the open assembly locations on the two tiles/substructures are updated and labelled *match* (all applicable assembly locations, including their rotational properties in the 3D case, must match when adding two substructures). This process repeats until all assembly locations are set to either match or unmatchable. At the end of a time interval, the resulting structures are placed in a single grid environment to determine if boundary violations occur. Before starting the next time interval, all unmatchable information locations are reset. The algorithm repeats, and halts when all time intervals have been completed in sequence.

An added constraint to the 3DscTAM is that substructures (with three or more components) cannot assemble together. This constraint represents observations in preliminary physical experiments conducted by the authors.

## Level Three: Physical Realisation of Rule Set

Components are physically realised using rapid prototyping, at level three. Both 2D and 3D components are defined by their design space (set of physically feasible designs, Fig. 4

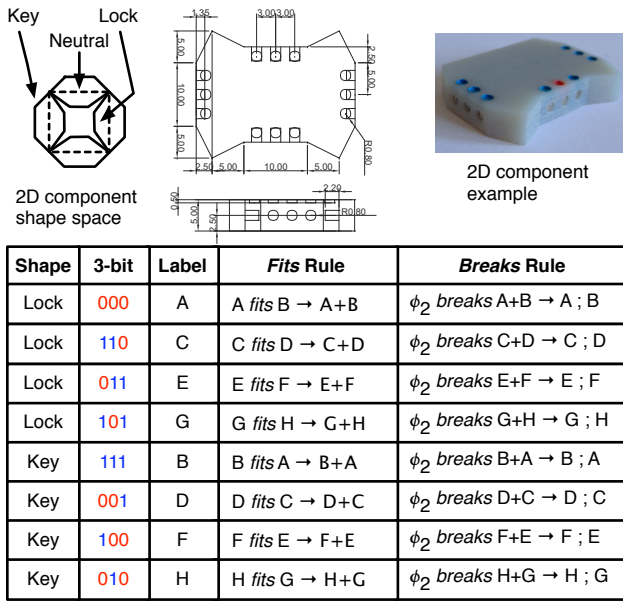

Figure 4: 2D component specification (construction units in mm), and 2D interaction rules (where red/zero and blue/one represent magnetic south and north respectively, and ' $\rightarrow$ ' transition, '+' assembly, and ';' disassembly).

and 5). The design space is a combination of a shape and an assembly protocol space. For both 2D and 3D components, a key-lock-neutral concept defines the shape space. A linear 3-magnetic-bit and a planar 5-magnetic-bit encoding scheme define the assembly protocol space for 2D and 3D components respectively. Magnets are placed within the edges or faces of 2D and 3D components respectively, and are not flush with a component's surface. The result of an air gap allows for adjustable component interactions and selective bonding (Whitesides and Gryzbowski, 2002). Although Miyashita et al. (2009) investigated how component shape and magnetic bonding affects the self-assembly process, they did not consider this morphological information in the context of staged self-assembly.

Here, lock-to-lock interactions can never occur due to their shape. This shape characteristic is influential in assigning 3-magnetic-bit and 5-magnetic-bit encodings to keys and locks. One magnet is placed in each position associated with a key, and two magnets are placed in each position associated with a lock. Strong bonding is ensured for key-to-lock interactions, and weak bonding between key-to-key interactions. The potential occurrence of weak bonding can be reduced with an appropriate physical temperature setting.

The four pairs of complimentary 3-magnetic-bit encodings can be optimally assigned to keys and locks to reduce assembly errors, as any key-to-lock error is at worst a one out of three match. Since this is not above a 50% match, bonding will not occur. Whereas the six pairs of unique

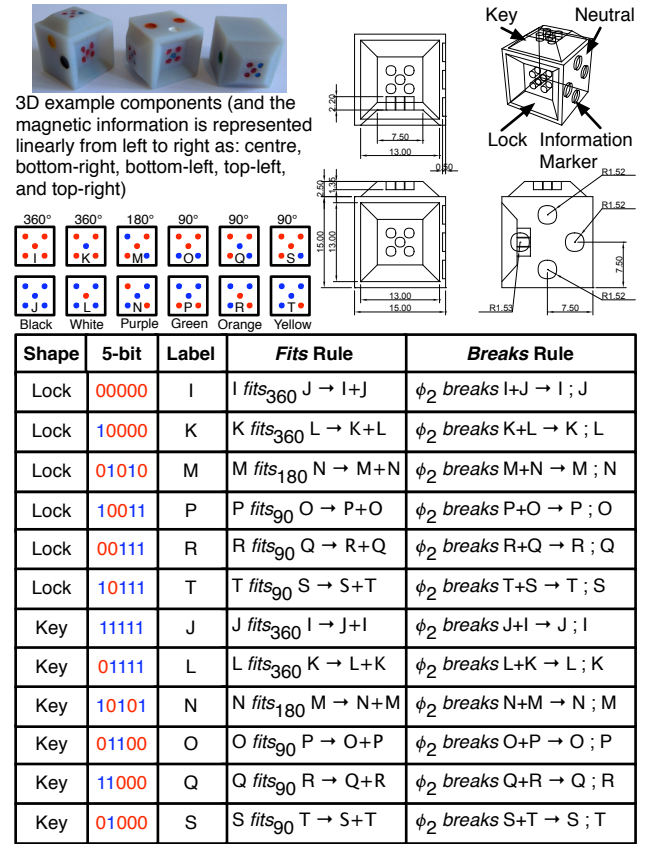

Figure 5: 3D component specification (construction units in mm), and 3D interaction rules (where red/zero and blue/one represent magnetic south and north respectively, and ' $\rightarrow$ ' transition, '+' assembly, and ';' disassembly).

complimentary pairs of 5-magnetic-bit encodings (accounting for planar rotation of a component's face) cannot be optimally assigned to keys and locks to reduce assembly errors. In this case, optimal assignment is considered with respect to which encodings are included to construct a target structure. It should be noted that these six encodings encapsulate rotational information for 3D component-to-component interactions, where two pairs encapsulate 360°, one pair encapsulates 180°, and three pairs encapsulate 90° rotational interactions. The 90° encodings have the potential for self-errors between complementary pairs, i.e. a three out of five match. A physical temperature to break three out of five matches, while maintaining five out of five matches, is strived for.

Orbital shakers form the environments for both 2D and 3D components. 2D components are placed on the surface of a tray, and a lid is used to prevent component reflections. 3D components are placed in a jar of mineral oil, to allow components to move freely in 3D space, and prevent oxidation affecting the magnets. The designs for both environments result from earlier experiments conducted by the authors.

Figure 6: Four target structures for the experiments.

## Experiments and Results

We present four experiments that were conducted to test our approach to staging the self-assembly process using morphological information. The purpose of these experiments is to demonstrate, as proof-of-concept, that staging can enable the self-assembly of closed target structures not otherwise possible. Closed refers to structures with defined boundaries (Whitesides and Gryzbowski, 2002). A target structure was assigned to each experiment (one 2D and three 3D experiments, Fig. 6). Here, the self-assembly process is staged (divided) into two time intervals, where components are only added to a one-pot-mixture environment. Component physical features, such as key and lock shapes and magnetic-bit patterns, are morphological information.

The independent variable is the use of two time intervals. The dependent variable is the resulting self-assembled structures. Enough components are supplied to create one 2D target structure and two 3D structures (due to boundary constraints of the environment). Ten trials are run for each experiment. A virtual trial (level two) is evaluated to being successful if all the potential number of target structures are achieved. A physical trial (level three) is evaluated to being successful if at least one target structure is achieved. The staging strategies and level one rules were designed by the authors. 2D and 3D experimental procedures and results are provided in terms of the three-level approach.

### Two-Dimensional System

The staging strategy for creating the 2D  $3 \times 3$  square target structure is to construct the *centre* and *edges* of the square in the first time interval, and construct the *corners* of the square in the second time interval (Fig. 7). In the first time interval, potential errors between the edge components can be reduced by appropriate selection of 3-magnetic-bit codes and the use of lock shapes to assemble to the centre component. The morphology of the substructure after the first time interval has corner features that can reduce assembly errors with the use of corner components that use only lock assembly shapes. The neutral edges of the corner components effectively block a corner component from assembling to the substructure in an improper orientation (Fig.7).

### 2D Level One Definition of Rule Set for Experiment

Fig.7 provides the component rules. The control group represents components that were not divided into time intervals

Target Structure	Staged Component Set
I	$\psi_0 \{1 \times (D,D,D,D), 4 \times (B,-,B,C)\}$ $\psi_1 \{4 \times (-,A,A,-)\}$

Figure 7: Staging strategy for target structure I, and error prevention due to shape and proper 3-magnetic-bit pattern selection (e.g. avoid magnetic repulsion configuration).

(non-staged). The experimental group used the same components, but divides them into two time intervals (staged). Interaction rules from Fig. 4 were applicable to both groups.

**2D Level Two Experimental Setup** The components from Fig.7 were mapped to an abstract representation for the 2DscTAM. Each component's shape was a unit square. The size of the environment was  $10 \times 10$  units (as a representation of width  $\times$  depth, and the ratio between component and environment size). A different random seed was used to initialise the 2DscTAM for each trial.

**2D Level Two Experimental Results** The staged components successfully created one target structure in each of the ten trials. None of the non-staged components were able to create one target structure. The unsuccessful non-staged trials either resulted in a set of substructures (due to edge and corner components assembling in incorrect orientations), or the creation of a  $3 \times 3$  open square. The results at level two were analysed using Fisher's Exact Test (one sided) for binary data (Cox and Snell, 1989). The results are statistically significant with a p-value of 0.

**2D Level Three Experimental Setup** A level three translation was preformed for both the staged and non-staged components (to observe the physical results of non-staged components). Components were mapped following Fig.7.

An Eden 333 Polyjet rapid prototyping machine was used to fabricate the components from Vero Grey resin. Neodymium (NdFeB) disc magnets ( $1/16'' \times 1/32''$ , diameter  $\times$  radius; grade N50) were inserted into the components. Blue/red paint (north/south) marked the magnets.

The environment size was mapped in accordance with the base component's size, to specify the dimensions of the circular tray environment. The tray was fabricated using a Dimensions Elite rapid prototyping machine, using ABS plas-

tic (sparse-fill option was used to create a rough surface texture). The outer radius of the tray is 135 mm and the inner radius is 125 mm, while the outer wall height is 9 mm and the inner wall height is 6 mm. The tray was mounted to a Maxi Mix II Vortex Mixer (using a tray mounting bracket, also fabricated using the Dimensions printer). A tray lid was cut using a Trotec Speedy 300 Laser Engraver laser cutting machine, using 2 mm clear acrylic sheet. The tray lid was secured to the tray using polycarbonate screws and wing nuts.

Each physical trial followed seven steps (Bhalla et al., 2010). (1) Set the speed control on the Maxi Mix II Vortex mixer to 1,050 rpm. This speed created an appropriate shaking level (environment temperature) to maintain fits rules, and to mostly break partially matched magnetic codes. (2) Secure the mixer to a table, using a 3" c-clamp and six hex nuts (to help secure the c-clamp to the back of the mixer). (3) Randomly place components on the surface of the tray (trying to ensure that complementary bonding sites on the components are not in-line with each other). (4) Secure the tray lid. (5) Run the mixer for 20 minutes for a non-staged trial, or for two 10 minute intervals for a staged trial. (6) Turn the mixer off. (7) Record the state of the system, observing: the number of target structures created, the number of matching errors (between conflicting physical information, where no fits rule is applicable), and the number of assembly errors (partial attachment between corresponding physical information, where a fits rule is applicable).

**2D Level Three Experimental Results** The level-three results are provided in Fig. 8, with an example of the end of each time interval of a successful trial. For both component groups, no matching and assembly errors were observed in the ten trials. Only partial structures were observed, and no open  $3 \times 3$  squares, were observed at the conclusion of the non-staged trials. Using Fisher's Exact Test, this experiment is statistically significant at the 0.01 level (i.e. there is a 99% certainty the results are not due to chance).

### Three-Dimensional Systems

The three 3D target structures have a three component common *core* structure, and vary in the number of *periphery* components (increasing from two, three, and four). The core structure requires two specialised  $90^\circ$  bonds, whereas the perimeter components only require general  $360^\circ$  bonds. As observed by the authors in preliminary 3D experiments, substructures consisting of at least three components are not able to assemble together. Given that the likelihood of general  $360^\circ$  bonds occurring is more likely than specialised  $90^\circ$  bonds, the staging strategy for creating the three 3D target structures is to construct the core substructure in the first time interval, and construct the periphery substructures in the second time interval (Fig. 9). The first time interval leverages the specialised component rotational information. Lock shapes for the  $360^\circ$  bonds are used as part of the mor-

Target Structure	Group	Successful	Unsuccessful
I	staged	7	3
	non-staged	0	10

Figure 8: Successful target structure I example trial, and the number of successful/unsuccessful 2D trials.

phology of the components in the first time interval, to reduce potential matching errors between specialised and general bonds. Furthermore, the resulting morphologies of the resulting core substructures at the end of the second time interval consist only of neutral and lock shapes, preventing assembly between the core substructures.

### 3D Level One Definition of Rule Set for Experiments

The component rules for the 3D experiments is provided in Fig. 9. Control groups and experimental groups represent non-staged and staged (using two time intervals) component sets respectively. The environment temperature was one. The interaction rules from Fig. 5 applied to both groups.

### 3D Level Two Experimental Setup

The components from Fig. 9 were mapped to an abstract representation for the 3DscTAM. A component's base shape was a unit cube. The size of the environment was  $4 \times 4 \times 4$  units (representing width  $\times$  depth  $\times$  height, and the ratio between component and environment size). A different random seed was used to initialise the 3DscTAM for each trial.

### 3D Level Two Experimental Results

The staged components, for each experiment, successfully created two target structures in each of the ten trials. Whereas, the non-sateged components were not able to create a target structure. As expected, the unsuccessful non-sateged components resulted in substructures consisting of three components (favouring assemblies with  $360^\circ$  bonds) or two components. The results at level two are statistically significant with a p-value of 0 using Fisher's Exact Test for binary data.

### 3D Level Three Experimental Setup

As with the 2D experiment, a level-three translation was performed for both staged and non-staged components (to observe the physical results of non-staged components). Components were

Figure 9: Staging strategy for target structure III (applicable to target structures II and IV).

mapped following Fig. 9, and were fabricated using a similar procedure as the 2D components (with the addition of colour paints to represent rotational information, Fig. 5).

500 mL clear glass, wide-mouth jars with rubber lined lids were used to contain components (91 mm×95 mm; diameter×height). A Trotec Speedy 300 Laser Engraver was used to construct the parts, using 3 mm acrylic sheet, for the jar rack. The rack was assembled using adhesive, screws, and hex nuts. The jar rack was placed on a New Brunswick Scientific Excella E1 Platform Shaker. 325 mL of Rogier Pharma light mineral oil was measured using a graduated cylinder, and poured into the jars (one for each experiment).

Each physical trial followed six steps. (1) Place three jars of mineral oil on the jar rack. (2) Randomly place the components for each experiment into the appropriate jar. (3) Secure the jar lids. (4) Turn the shaker on by setting the speed to 32.5 rpm. (5) Run the shaker for 40 minutes for a non-staged trial, or for two 20 minute intervals for a staged trial. (6) Record the state of each system, observing: the number of target structures created, the number of matching errors, the number of assembly errors, and the number of rotation errors (between complementary components).

**3D Level Three Experimental Results** The 3D level-three results are provided in Fig. 10, along with examples of the end of each time interval of a successful staged trial. For each experiment, no matching and assembly errors were observed in the ten trials. Rotational errors were observed in each staged experiment (Fig. 11). Using Fisher’s Exact Test, the first two 3D experiments are statistically significant at the 0.05 level and the third experiment was statistically significant at the 0.50 level (i.e. there is a 95% and 50% cer-

Target Structure	Group	Successful	Unsuccessful
II	staged	4	6
	non-staged	0	10
III	staged	5	5
	non-staged	0	10
IV	staged	1	9
	non-staged	0	10

Figure 10: Successful target structure II, III, and IV example trials, and the number of successful/unsuccessful 3D trials.

tainty the results are not due to chance). Even though one successful staged trial was observed with the third 3D experiment, we do not consider the result statistically relevant.

**Discussion** Four experiments were conducted to demonstrate our morphological information based staging strategy. At level two, all of the staged components sets were able to achieve their respective target structures, whereas none of the non-staged components were able to. All the staged component sets, except for the third 3D experiment, were able to successfully construct their respective target structures at a statistically significant level (with 99% and 95% confidence for the 2D and 3D experiments), at level three.

One physical target structure was achieved in the third 3D experiment, and we observed in the trials a *layering effect* of components/substructures that inhibited the self-assembly of this target structure (IV). As future work, we look to build neutrally buoyant components to address this issue.

Figure 11: Rotational errors at the end of each 3D trial (target structures II blue, III red, and IV green).

We are also investigating the use of higher-order magnetic-bit codes, additional magnetic-bit patterns, and new methods for creating a more suitable physical environment temperature to prevent the occurrence of rotational errors.

An implication of staging is on the self-repairing properties of a system. Although we observed the 2D  $3 \times 3$  square being able to self-repair, this was only within the second stage. Further research into features that allow for, and the understanding of the limits to, self-repair between specific stages is required to continue to further develop our approach. For example, although salamanders undergo development through unique stages, they can regrow lost limbs by repeating earlier developmental stages (Wolpert, 1998).

Nevertheless, we envision our staging strategy being applicable to a variety of applications relying on fixed components, such as the design of nano and microscale structures, circuit design, and DNA computing using self-assembly. Moreover, we envision our staging strategy as an approach to improve the ability of artificial evolution for the creation of more complex physical self-assembling systems.

## Conclusions

Staging is an essential part of biological development. In this work we presented a novel approach to staging the self-assembly process using morphological information. This work involved creating two new staged self-assembly analytical tools, the 2DscTAM and the 3DscTAM. Furthermore, this work showed how the interplay between component morphological information (shape and magnetic patterns) can be used to reduce assembly errors and leverage rotational properties by using staging. We presented four proof-of-concept experiments to demonstrate that our staging strategy is a viable method for enabling the self-assembly of more complex morphologies not otherwise possible.

## Abstract

In this work the question of whether the introduction of both transcription errors and cultural transmission, in the form of learning by imitation, can enable the evolution of behaviours *inaccessible* to incremental genetic evolution alone is assessed. To answer this a neural network model using a hybrid of two different networks was implemented: one capable of demonstrating reactive qualities, the other controlling deliberative goal selecting behaviours. Animats using this model were evolved in an adaptation of the environment proposed by Robinson et al. (2007) to solve increasingly difficult tasks. Simulations were run on populations with and without learning by imitation to assess the relative success of each strategy, leading to the conclusion that populations with learning by imitation can successfully demonstrate the most complex behaviour, which was empirically found to be inaccessible to non-learning populations.

## Introduction

In this paper we present work showing animats in a virtual environment learning behaviours through imitation that are inaccessible to incremental genetic evolution alone. Learning by imitation is often considered to be a mechanism of social information transfer (Cavalli-Sforza and Feldman, 1981; Whiten and van Schaik, 2007), leading to what may be described as social or cultural learning. By combining population learning and individual learning in the same evolutionary system it is possible to make use of both global and local search: global search through the underlying (multi-generational) genetic algorithm and local search through individual (lifetime) learning (Hinton and Nowlan, 1987). It has been demonstrated by Best (1999) that by using cultural learning in place of individual learning on a more challenging version of the Hinton and Nowlan (1987) problem, it is possible to improve the speed at which a population of agents discover an adaptive goal. Cultural learning has the added advantage of allowing individuals to pass on learnt information to other members of the population, and so preserving extra-genetic information for the next generation. Beyond its uses in evolutionary optimisation and search, cultural and social learning is also a well known natural phenomenon with various species using social learning mech-

anisms such as imitation, emulation, teaching and the use of public information to produce adaptive behaviours in dynamic and challenging real world environments (Whiten and van Schaik, 2007; Reader and Biro, 2010).

A number of studies have investigated the effect learning by imitation has on populations of evolving neural networks (Best, 1999; Cangelosi et al., 2006; Acerbi and Parisi, 2006; Acerbi and Nolfi, 2007; Curran and O’Riordan, 2007; Marriott et al., 2010). In much of the literature these imitating neural networks are referred to as agents, with some, as is the case in this work, even taking on the role of animats or autonomous agents in virtual environments (Marriott et al., 2010). It is the aim of this work to investigate whether learning by imitation in a population of neural networks enables behaviours that are deemed to be inaccessible to incremental genetic evolution, to be learned and maintained. In order to test our claims an increasingly complex virtual environment is used in which animats’ behaviours are evaluated. It is expected that without learning these animats will only be able to exhibit a limited set of behaviours, whereas animats learning through imitation should evolve in such a way to allow access to all categories of behaviour.

## Incremental Genetic Evolution

Long-term incremental evolution necessarily uses converged populations, which can be referred to as species (or quasi species). In genetic algorithms (GAs) this is referred to as the Species Adaptation Genetic Algorithm or SAGA approach (Harvey, 2001). The SAGA approach impacts on the way populations evolve: recombination will have a far smaller effect on the motion of the population than in a standard GA, as each species is already genetically similar, leaving mutation as the primary driving force behind evolution. Mutation can be substantially effective in spaces percolated by neutral networks: pathways of level fitness through the fitness landscape. In this case genotypes can vary while still producing similar phenotypes and behaviours. When phenotypes of higher fitness are found the population converges onto them. This incremental approach enables species of animats to discover and converge upon an easily accessible

solution. However, if there is no neutral or incremental path between the corresponding basic behaviour and fitter ones, the population will struggle to move away from these sub-optimal behaviours. Figure 1 depicts a mock example.

One approach to solving the problem of sub-optimal convergence is to increase the rate at which mutation is applied, potentially allowing the population to explore more of the fitness landscape and so discover new fitness peaks. However, there are problems with this approach: as mutation rates increase, the evolutionary search strategy begins to resemble random search, with larger mutation rates making it increasingly difficult for the population to maintain solutions. The point at which mutation becomes so large that favourable structures discovered by evolution are lost more frequently than they are found is known as the error threshold. Ochoa et al. (1999) and others have demonstrated a link between error thresholds and optimal mutation rates in evolutionary algorithms.

### **Discovering and Maintaining Inaccessible Solutions: Transcription Errors and Imitation**

To solve the issue of sub-optimal population convergence without crossing the error threshold, noise is often added to the fitness landscape via the genotype to fitness map. However, where such noise is in the phenotype to fitness section of that map, its ability to aid in the transition between peaks (or more accurately between neutral networks) is limited. By instead incorporating noise into the genotype to phenotype map, as with transcription errors, behaviours inaccessible to incremental genetic evolution may be exhibited reliably by individuals while leaving the genotype untouched. It can be useful to view such noise as a type of unguided individual learning.

In order to maintain successful behaviours in the population, some form of extra-genetic learning needs to take place. The model employed in this work makes use of imitation through interactions between teachers and pupils to facilitate the transmission of learnt behaviours (Cangelosi et al., 2006; Acerbi and Parisi, 2006; Acerbi and Nolfi, 2007; Curran and O’Riordan, 2007). As in Curran and O’Riordan (2007) pupils follow teachers in a mock evaluation on a set of environments. As both teacher and pupil receive the same environmental input the teacher’s output may be used as a target pattern for error backpropagation, reducing the pupil’s output error compared to that of the teacher. By learning in this way pupils are able to imitate the behaviours exhibited by teachers, thus maintaining behaviours in the population that would have been lost in incremental genetic evolution.

### **Neuroevolution of Deliberative Behaviours**

This work uses populations of neural networks embodied in animats. The neural network architecture used here is a hybrid of two different networks: the first controlling the high level deliberative behaviours of the animat, and the sec-

ond controlling the animat’s reactive capabilities (Robinson et al., 2007). By making use of both reactive and deliberative mechanisms, neural architectures of this sort are able to seek long term goals while also reacting to unforeseen events ultimately enabling the evolution of complex problem solving abilities. To demonstrate these problem solving abilities Robinson et al. (2007) developed a complex problem called the ‘river crossing’ or RC task. The RC task required animats to find a single reward-giving *Resource* in a 2D grid-world environment containing a number of obstacles. Alongside *Resource* objects animats could encounter *Water*, *Grass*, *Traps* and *Stones*. Grass objects made up the majority of the environment and were seen as neutral space for the animats to move across; Trap objects were immediately lethal, as were Water objects, which were placed in such a way to resemble an unbroken river cutting the animat’s path to the *Resource*. In order to cross the river animats were required to pick up Stone objects, which could be carried at no cost to the animat, and place them in the same cells as Water thus negating their lethality. Once a continuous bridge of Stones over the river had been built animats could access the *Resource*. To succeed at the RC task animats were required to evolve with no *a priori* knowledge of the world; each new environment was unique and animats had no concept of co-ordinates, making solutions such as ‘move five steps to the right’ impossible, instead animats evolved goals and sub-goals such as ‘go to resource’, ‘avoid traps’ or ‘head to nearest stone’ which then allowed the network to navigate the animat towards these goals. Despite the RC task being reasonably complex, Robinson et al. (2007) demonstrated that it could be solved by initially converged populations of animats using only incremental genetic evolution. To test our hypothesis a more complex version of the RC task has been developed: the RC+ task.

### **The RC+ Task**

An important aspect of the RC task was that individuals were evaluated on increasingly difficult environments. In Robinson et al. (2007), animats were first shown a map with no river blocking their path; then a river with a width of one cell was introduced, followed by a final environment containing a river with a width of two cells. Stone and Trap objects were of a consistent number throughout all tests giving animats equal exposure in each environment. The RC+ task makes the task harder in regard to both river width and exposure to Stone objects. The number of environments an animat is evaluated on is increased from three to five, with environments becoming increasingly difficult to solve due to river width increasing from zero cells to four cells. To add to the difficulty further, the number of Stone objects gradually decreases from twenty in the first environment to zero in the final environment, making each environment more challenging to the point where the final environment cannot be completed by building a bridge. In order to make the final envi-

Fig. 1: A species starting from point X on the above mock fitness landscape would achieve peak A by way of the hill climbing strategy adopted by incremental genetic evolution (driven primarily by mutation and selection). Gradient-based learning amongst such a species would ordinarily also be restricted to peak A. The inclusion of both noise in the genotype to phenotype map and learning by imitation can enable the species to jump across areas of lower fitness to higher peaks (inaccessible to hill climbing alone), where incremental genetic evolution and learning can resume hill climbing.

environment solvable two extra objects, *Object A* and *Object B*, are introduced into the environment. *Object A* and *Object B* are rare objects, with only one instance of each found in each environment. Like Stones, *Object A* and *Object B* may be carried at no cost to the animat and placed upon any square or object. If an animat happens to place both *Object A* and *Object B* on a square containing Water (notionally forming a floating raft that carries the animat to the resource), a reward equal to that of the Resource is received and the animat is considered to have successfully solved the environment. In short, an alternate Resource may be constructed out of the three other objects (*Object A*, *Object B* and Water), removing the need to build bridges but still requiring agents to be driven towards the Resource when Water is not present. The RC+ task is impossible to solve with incremental genetic evolution alone. To solve it, animats are required to engage with Water, *Object A* and *Object B* while still avoiding Traps and uncovered Water, and to also be able to reach the Resource in the absence of Water (the simplest sub-solution to evolve). The rarity of both *Object A* and *Object B* adds to the difficulty of the RC+ task as animats must now evolve to be driven to towards *Object A* and *Object B* despite potentially very little exposure during their time in the environment.

### The Model

Animat movement is controlled by a hybrid neural network embodying both reactive and deliberative qualities. This hybrid network may be broken down into two network models: a *shunting network* and a *decision network*, with the decision network passing information on to the shunting network which in turn controls the animat's movement. The

shunting network is not directly exposed to any evolution or learning. The deliberative network on the other hand is exposed to both evolution and learning, enabling the evolution and inheritance of animat behaviour.

### The Shunting Network

Shunting networks are a specialised form of neural network making use of what is known as the shunting model (Yang and Meng, 2000). The inspiration for the shunting model came from Yang and Meng's (2000) desire to develop motion planning systems capable of reacting quickly in real-time environments, thus allowing robotic agents to exhibit robust and collision-free motion planning behaviours. Instead of directly specifying behaviours, the shunting model maps network outputs onto environmental outputs (within an internal map of the environment) which are propagated across the environment to form an activity landscape. This activity landscape is used by the agent to control movement through the environment, by dynamic gradient ascent of the landscape. In their model, Yang and Meng (2000) demonstrated a neural network composed of an  $n$ -dimensional lattice of neurons, with each neuron representing a possible state in the system. By using neurons to represent states in this way it is possible to represent any system which is capable of being fully described by a set of discrete states.

The environment used for the RC and RC+ tasks is a simple 2D grid-world consisting of  $20 \times 20$  cells, with each cell representing a position in co-ordinate space. Each position in the grid-world may be occupied by any number of objects found in the RC+ environment (Resource, Water, Trap, Grass, *Object A* and *Object B*), allowing the system to be fully described by a set of discrete states, thus enabling the

use of the shunting model to direct animat movement across the RC+ environment and ensuring a simple one-to-one relationship between neurons and geographical locations.

In Yang and Meng (2000), two versions of a transition function for specifying inter-neuron dynamics were developed: one which controlled activity saturation in the network and one which did not. Consistent with the findings of Robinson et al. (2007), we found activity saturation not to be a problem exhibited by networks in the RC+ task, enabling the use of the simpler transition function in equation 1.

$$\frac{dx_i}{dt} = -Ax_i + I_i + \sum_{j=1}^k w_{ij} [x_j]^+ \quad (1)$$

Alpha ( $A$ ) represents the passive decay rate, which determines the degree to which each neuron's activity diminishes towards an idle state. The functions  $[x]^+$  is  $\max(0, x)$ . The connection weight (or synapse strength)  $w_{ij}$  between neurons  $i$  and  $j$  is the Euclidean distance between cells  $i$  and  $j$  within the receptive field.  $k$  is the receptive field size and here is set to 4, corresponding to the four cells orthogonally surrounding cell  $i$ . Iota ( $I$ ) is equal to  $E$  in the case of the target, and  $-E$  for an obstacle, where  $E$  is a large integer.

In the case of the RC and RC+ tasks Iota values are limited to 15, -15 and 0, representing the target resource, an obstacle and neutral space respectively. The result of using a transition function with these values are 2D environments with large peaks at the sites of target states, large troughs in cells occupied by obstacles, and large amounts of neutral space through which neuron activity from targets may spread. Using the shunting model to control animat movement allows for goals such as 'head for resource while avoiding traps' or 'place carried stones on water' to be easily achieved.

## The Decision Network

The role of the decision network is to set the Iota values for object states found in the RC and RC+ task. Using the decision network animats can set the desirability of object states in relation to their current environmental inputs, allowing them to manipulate the shunting network's activity landscape and so combine multiple actions such as 'pick up the closest stone' and 'place stone on water' to create complex behaviours.

As in Robinson et al. (2007), the decision network is simply a feed-forward multi-layer perceptron with one hidden layer comprising of four hidden units. The input layer is capable of representing the animat's current state in the environment including whether or not the animat is currently carrying a movable object (Stone, Object A, Object B), with each movable object having a dedicated carrying input. Inputs taken by the input layer are single values of 1 or 0, representing the presence of the object in the same cell as the animat. These input values are fed through to the hidden layer neurons via weighted connections in the range

$[-1,1]$ . At each hidden unit the weighted sum of inputs is passed through a hyperbolic tangent activation function to produce hidden layer outputs. In the RC+ task the output layer is made up of sixty-seven neurons representing the Iota values of all sixty-four possible environmental states (excluding Grass objects whose Iota values are always set to 0 and therefore do not need be represented in the decision network) and a pick-up/put-down output for each non-static object (Stone, Object A, Object B). At each output neuron the sum of all weighted connections is passed through a hyperbolic tangent activation function with fixed thresholds: neurons outputting within the range  $[-0.3:0.3]$  are set to output 0, while all outputs over 0.3 resolve to 1 and all outputs below -0.3 resolve to -1.

For outputs representing the pick-up/put-down actions output values of -1 cause the animat to put down the specified object they are carrying, values of +1 causing animats to pick up the movable objects they are currently sharing a cell with providing the animat is not already carrying an object of that type. For all other outputs, resolved output values set the Iota values to be used in the shunting network. So if an output neuron has a negative output, all objects of that class found in the environment at that point in time will have their activations set to -15; for positive outputs to +15. Any object resulting in an Iota value of 0 will remain neutral, causing their activation values in the shunting network to be solely based on the propagated activations of other objects. The resulting environment will contain a number of peaks of high activity and troughs of low activity, gradually propagating activity through neighbouring neutral cells.

Figure 2 shows two of the five potential environments an animat may observe in the RC+ task, and the corresponding activity landscapes given certain outputs from the decision network. The first environment represents the initial challenge an animat must complete, where only traps stand in the way of a resource. As can be seen by this environment's activity landscape, the Iota value associated with the resource has been set to be positive resulting activity propagating from the resource over the surrounding neutral space. The second environment represents the second challenge, to cross a river before having access to the resource. In this environment's case, activation propagation from the resource has been impeded by the decision network outputting negative Iota value for Water objects. Negative activity repels animats from objects with negative Iota values; however positive activation can be seen coming from the Object B object, providing a hill-climbing route for the animat to take in activity space.

## Evolution of the Decision Network

To evolve the decision network a steady-state genetic algorithm was used. At each iteration two animats were selected from the surviving population to be evaluated in tournament selection, with the worst performing animat being

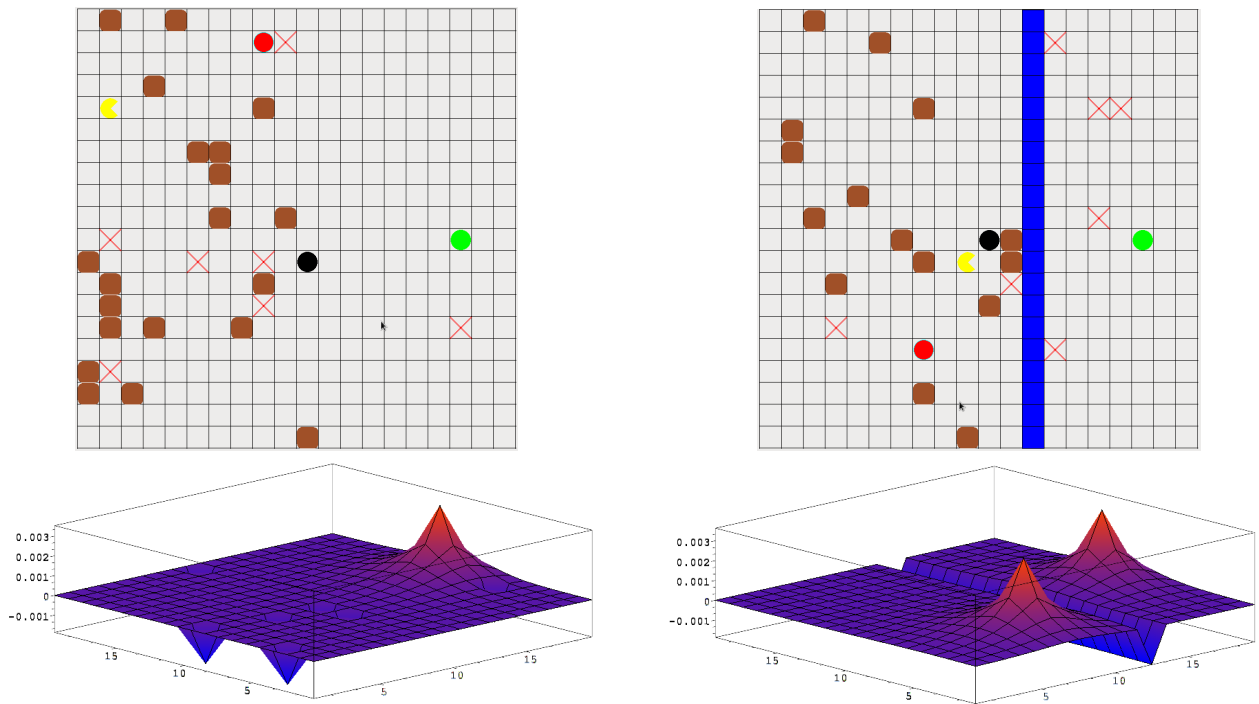

Fig. 2: Two environments with their activity landscapes (given certain outputs from the decision network - see main text). Animat=yellow, Stones=brown, Resource=green, Object A=black, Object B=red, Traps=crosses, Water=blue.

replaced by the progeny of the better performer. The competing animats are evaluated in five increasingly difficult environments. If during evaluation an animat fails to complete an environment, the evaluation is terminated. Fitness is set to be the number of environments successfully completed by an animat during evaluation.

An animat's genotype consists of a set of floating point values each in the range  $[-1,1]$ , which are transcribed into the connection weights in the animat's decision network. The genotype and the decision network are stored separately, so any learning that may take place during an animat's lifetime will only affect the decision network: no changes are made to its genotype after an animat is initially created. New animats are the offspring of two other animats from the current population: one tournament winning animat and one randomly selected animat. The child's genotype is created first through recombination of the parents' genotypes; for this operation single-point crossover is used with the point of crossover being a randomly selected point in either parent's genotype. Each loci in an animat's genotype represents exactly the same connection weight as in any other animat's genotype, with all genotypes being of length  $L = 308$ . Mutation follows recombination; each point has a probability  $P_{\text{mut}} = 1/L$  of having a random value from  $N(0,0.4)$  added to it, with the resulting values being bounded within the range  $[-1,1]$ . Once the genotype has been constructed it is written to the new animat's decision network; this process is

referred to as transcription. During transcription two randomly selected connection weights are overwritten with a new random value selected from a discrete uniform distribution  $U(-1,1)$ . The weights now present in the decision network dictate the animat's future behaviours within each environment.

### Learning in the Decision Network

Following reproduction new animats are afforded the opportunity to learn from a teacher via error-backpropagation. This method of teacher-pupil backpropagation has been previously employed by Curran and O'Riordan (2007). However, the teacher-pupil scenario used in this work differs in a number of ways. In the learning model used by Curran and O'Riordan (2007), teachers were selected from the population based upon their fitness and then assigned  $n$  pupils to teach. We contend that in nature absolute fitness is very difficult to assess. To resolve this issue, the current tournament-winning parent is assigned the role of teacher, with the parent's most recent progeny assigned the role of pupil.

There are also differences in the way error-backpropagation is used to teach pupils in this model compared to that of Curran and O'Riordan (2007). As with our model, Curran and O'Riordan (2007) allowed pupils to hitchhike on the back of the teacher during a mock evaluation, with inputs shared between teacher and pupil and using the teacher's output pattern as a target pattern

for the pupil to learn. The learning method employed by Curran and O’Riordan (2007) permitted pupils to learn from the target pattern until the error between child and parent outputs were minimised to a satisfactory level. In our model pupils are only presented with the current teacher’s output once every simulation time step (immediately after the teacher’s decision network’s inputs, activations and outputs are updated). If a teacher happens to move through the environment in such a way that both inputs and outputs remain the same, the child will be presented with many opportunities to learn a given target input-output pattern. However, if the teacher moves around the environment via many different input combinations, the student will have the opportunity of potentially witnessing many different target outputs but at the cost of having very little time to minimise error. Imitating in this manner enables the population to retain favourable behaviours not coded for genetically, whilst not undermining the incremental genetic evolutionary process.

## Experimentation

At each iteration of the model two individuals are taken from the population to be evaluated on a series of five environments/maps. All maps have seven Trap objects placed randomly on the map, one reward-giving Resource, one Object A, one Object B, and  $20 - (5 \times \text{riverwidth})$  Stone objects. River width varies from an initial width of zero, increasing by one cell per map. During evaluation individuals must successfully reach the Resource or place Object A and Object B onto a cell containing Water; any animat failing to do so within 100 steps or dying by means of a Trap or uncovered Water is not permitted to attempt the next environment.

Fitness in the model is determined to be the number of maps successfully completed in the current tournament iteration, with individual fitness being set to zero before each evaluation. The individual achieving the highest fitness is allowed to reproduce, with the weaker individual being replaced by the progeny of the tournament winner and a randomly selected animat. This steady-state approach maintains the population at a size of 100 individuals.

After reproduction the child is allowed to learn via error-backpropagation from its tournament winning parent. The child follows its parent in a mock evaluation, with the child’s inputs being set to those of the parent. Learning takes place for as long as the parent is being evaluated. Once the parent either fails to complete a map or completes all five environments, learning is terminated. At each step through the evaluation the child attempts, via error-backpropagation with a learning rate of  $\delta = 1$ , to learn to imitate the parent’s output for the current inputs.

Three strategies are used in this model: two without learning and one with learning. Populations of animats with no access to learning fall into two categories. The first, known as *Non-Learners(1)*, having a mutation rate and transcrip-

tion error equal to that use by learning populations. As populations of *Non-Learners(1)* have no way of assimilating transcription errors back into the genotype it may be seen as giving learning populations, known as *Learners*, an unfair advantage. With this in mind a second of category of non learners, known as *Non-Learners(2)*, are also evaluated. *Non-Learners(2)* do not have transcription errors, and instead have a mutation rate equal to that of the original mutation rate plus two transcription errors:  $P_{mut2} = 3/L$ .

To test the ability of each strategy to exhibit the behaviour necessary to complete the most difficult map, fifteen populations of each learning strategy were simulated. Each simulation lasted a maximum of 5,000,000 tournaments. In each simulation the best individual’s fitness and the mean population fitness were recorded at intervals of 500 tournaments. The maximum fitness an individual could achieve was five, which directly relates to the successful completion of all five evaluation environments, the fifth environment being impossible to complete by bridge building and so requiring the combination of Object A and Object B on Water. For a population to be considered as adequately completing the fifth map, a fitness of five must have been recorded by the fittest individual at ten recorded tournaments with at least five of these tournaments being unbroken by a sub-optimal result. This ensures that the complex behaviour tested for is not only found but also maintained by the population.

## Results

Table 1 shows results from the fifteen populations of animats using the *Non-Learners(1)* strategy: the mean, best and worst number of tournaments required to solve each map, across the fifteen populations (runs), and the proportion of populations that were successful in solving each map. Of the *Non-Learners(1)* populations over 90% were able to complete maps 1 to 4 but no population was able to demonstrate a successful solution to map 5. Populations of animats using the *Non-Learners(2)* strategy also demonstrated a high level of proficiency when completing maps where the bridge building solution is effective, though with a lower proportion of populations able to complete map 4 (see table 2). This may be due to the higher mutations rate used in the *Non-Learners(2)* strategy causing the destruction of potentially beneficial behaviours before they can proliferate through the population. To complete map 4 animats had to be stricter (more consistent) in their use of Stone objects. Despite this behaviour being reachable using incremental genetic evolution it is within a small area of weight-space, causing it to be potentially lost with higher mutation rates. Neither non-learning strategy was able to discover the precise behaviour necessary to complete map 5, so failures recorded in tables 1 and 2 were not due to a sufficient behaviour being discovered but not maintained: the map 5 solution was simply never found, empirically demonstrating the inaccessibility of map 5 to incremental genetic evolution alone.

Map	Mean	Best	Worst	Stdev	Success
1	1200	500	3500	996	100%

Tab. 2: Non-Learners(2): Mean, best, worst number of tournaments required to solve each map.

Table 3 shows results from animats using the Learners' strategy. Unlike non-learning strategies, Learners are able to complete map 5 and thus exhibit the complex behaviour tested for in this work a third of the time, proving the hypothesis that learning by imitation is capable of enabling populations of animats to discover behaviours found to be inaccessible to incremental genetic evolution alone. However, Learners are seemingly less likely to discover and maintain solutions to maps 3 and 4 than non-learning animats.

Figure 3 charts the mean fitness of the best performing population from each learning strategy. From this graph it can be observed that Learners bypassed the sub-optimal bridge building solution once the population had (for some time) been evaluated on maps with rivers. The incremental nature of the evolution in this model causes the majority of the population to rapidly converge on the optimal solution once it has been discovered. Without learning, this optimal behaviour cannot be found. In this model incremental genetic evolution leads to convergence on sub-optimal solutions in non-learning populations, making it impossible for the discovery of the optimal behaviour. By combining learning by imitation and incremental genetic evolution in a

Populations learning by imitation demonstrated the ability to converge on more complex behaviours, thus achieving a higher fitness. Neither non-learning strategy is capable of producing the more complex behaviour.

model such as the one presented here, it is possible to not only discover complex behaviours inaccessible to incremental evolution alone, but also to have rapid convergence to a population exhibiting and maintaining that behaviour, thus creating a behavioural tradition or culture (Whiten and van Schaik, 2007). The results found here are broadly consistent with those of Acerbi and Nolfi (2007), who found that the combination of individual and social learning in artificial embodied agents not only allowed for the development of difficult and costly behaviours, but also provided an adaptive advantage over individual learning alone and lead to cumulative cultural evolution.

## Conclusions and Future Work

If a learnt behaviour is exhibited and maintained throughout a population for a number of generations it may tentatively be called a tradition or even a culture. According to Whiten and van Schaik (2007) traditions are “consistent habits” that make use of social information transfer. In the model demonstrated here learning by imitation enables social information transfer with behaviours being maintained by converged populations or species giving rise to traditions. The limited set of behaviours observed in this population do not however constitute the category of culture, which is reserved for the maintenance of multiple behaviours by a species. The incremental nature of the model causes sub-optimal behaviours to be phased out of the population. Were greater environmental diversity to be used, it may be possible to evolve a culture rather than a tradition.

The hypothesis presented here was that the introduction of both transcription errors and cultural transmission in the

form of learning by imitation are sufficient to discover and maintain the most complex behaviour possible in the model, while incremental genetic evolution alone is not. The results prove our hypothesis by demonstrating that without learning by imitation the solution to the final environment is never found but with imitative learning all behaviours can be discovered, exhibited and maintained.

One drawback to the model used in this work is the limited set of behaviours available to animats. By using a larger environment with a greater variety of potential states available to the animats and evolving the size and structure of the decision network, it may be possible to demonstrate the evolution of multiple behaviours leading to the emergence of a culture. To investigate more complex behavioural development and the role of imitative learning in the evolution of traditions and cultures, it would be beneficial to implement larger and more dynamic environments and allow for greater evolution in the decision network. A secondary drawback was the simple vertical social transmission mechanism used. The inclusion of intra-generational or oblique cultural transmission has been shown to be both sufficient (Cavalli-Sforza and Feldman, 1981) and beneficial (Acerbi and Parisi, 2006) for the evolution of complex and robust cultural behaviours. Further investigation and application of oblique transmission within models such as that presented here would further benefit our understanding of and ability to achieve the evolution and maintenance of complex cultural traits.

## Abstract

Crowdsourcing, a real-life instance of human collective intelligence, is a phenomenon that changes the way organizations use the Internet to collect ideas, solve complex cognitive problems, and build high-quality repositories (e.g., Wikipedia) by self-organizing agents around data and knowledge. Many recent studies have highlighted the factors and the small sets of parameters that play a role when a large crowd interacts with an organization. However, no comprehensive simulation has yet been developed to incorporate all these parameters, investigate Artificial Life phenomena such as emergence and self-organization and potentially generate predictive power. Based on a presentation at ALIFE XII, this paper describes the development of a simulator for human crowds performing collective problem solving in a Crowdsourcing scenario. It introduces the mechanics of a multi-agent system (MAS) by building on insights from empirical science in several disciplines. The simulator allows running sensitivity analyses of multiple parameters as well as simulation of intractable interactions of complex networks of irrational agents. In addition, the paper provides a review of Crowdsourcing and human collective intelligence literature structured from an Alife point-of-view.

## Introduction

Many researchers in the Artificial Life community are researching self-organizing, decentralized systems (e.g., large groups of ants or vertebrates such as bison [*collective animal intelligence*]) that show, in their interactions, a high degree of (self-)stability and flexibility. Social scientists are transferring these insights to social networks and other interactions between humans (for examples, see Krause et al. 2010).

A Crowdsourcing scenario provides an excellent setting for investigating *human collective intelligence*, generated through networks of interactions among individuals and between individuals and the environment. “Crowdsourcing” (Howe 2008), an instance of collective intelligence (Buecheler et al. 2010, Robu et al. 2009) emerging from de-centralized actions of a community of users, is a phenomenon currently occurring all over the world, strongly benefiting from new technologies and the development of Web 2.0: In essence, a “seeking” entity (e.g., a company or university) seeks the support of an *apriori* unknown and potentially very large group of intelligent agents (i.e., humans) by posting its unsolved problems on the internet. A simple and famous example is the

Wiki Foundation (seeker) using internet users (crowd of solvers) to produce the world’s largest encyclopedia (Wikipedia) with high-quality results (Giles 2005). This can either happen directly, as with Wikipedia, or through “information brokers”, such as Innocentive.com or NineSigma.com that connect seekers and solvers through a platform. Small start-up companies as well as large established institutions (such as Fortune 500 companies and universities or other large organizations like NASA) are currently using Crowdsourcing for a variety of purposes. (Kittur et al. 2008) describe how user input can substantially improve the interaction design and how input after development can provide important feedback for continued improvement based on investigations on Amazon’s “Mechanical Turk”. Some examples where collective human intelligence is more useful than mere computational power by using “games with a purpose” are given in (von Ahn 2006).

The underlying complex dynamics are being intensively investigated by researchers from several disciplines, sometimes using different names like “Open Innovation” (Chesbrough 2003) or “Swarm Intelligence” (Dorigo and Stützle 2004, Krause et al. 2010) for slight variations of the phenomenon of interest. Recent studies investigate single parameters or specific settings of Crowdsourcing (e.g., Sieg et al. 2011, Leimeister et al. 2009, Alonso et al. 2008). However, so far there has been no comprehensive simulation of the complex interactions between agents involved in this scenario.

Phenomena relevant in an Artificial Life context such as self-organization, stigmergy and especially emergence, are very relevant when trying to understand complex dynamics between humans in real-life organizational scenarios (Bandtke 2007). The emerging phenomena in organizations are created through interpersonal, analytically irreducible factors such as spontaneity, informal structures and interactions, ad hoc processes and groups as well as informal conventions such as norms and similar social patterns. This paper describes the underlying dynamics of a complex Crowdsourcing system and an implementation in our simulator, based on a framework for multi-agent systems (MAS). The simulator uses parameters based on empirical studies and integrates a set of essential factors and rules of interactions between members of the “crowd” and the seeking entities. Hence, this paper also provides a structured literature review of Crowdsourcing parameters. Due to its modular set-up, the simulator allows for the addition of more factors, once understood by scholars, to

increase the accuracy of simulation runs and, potentially, its predictive power. The large set of rules and unpredictable outcomes, such as negotiation results between agents (modeled in the MAS), allow the observation and statistical evaluation of emergent phenomena.

In what follows we review the state of the art in Crowdsourcing and Open Innovation research and relevant multi-agent simulation topics, then explain which parameters we are modeling and introduce the simulator before discussing first insights, use cases, and potential next steps.

## State of the Art

We discuss three sections of prior literature: First, the application of swarm behavior and problem solving insights from biology to Crowdsourcing, then relevant insights from management and organization science, often published in the context of “Open Innovation”. In the third part, we look at theoretical and empirical evidence from other contexts that are also important for the creation of this simulator.

### Crowdsourcing, Communities and Group Behavior

(Krause et al. 2010) describes the advantages and challenges of transferring insights from biological studies to human social interactions. Similar to swarms, flocks, and herds, humans follow certain local rules of interaction in large groups. In a Crowdsourcing context, these local rules are evolving over time. Initially, chaotic behavior converges into social patterns and the crowd members use their local knowledge (similar to birds in a flock or fish in a school) to interact with other agents and contribute to Crowdsourcing. In most cases, the crowd self-organizes without a central body of control. Self-organization, as defined by (Camazine et al. 2003), states that “the rules specifying interactions among the system’s components are executed using only local information, without reference to the global pattern”, emerging from lower-level components of the system.

The crowd is especially good at solving coordination or cooperation problems (Surowiecki 2004). (Schelling 1960) investigated the reasons for this and found a possible explanation in focal points (“Schelling points”), towards which human expectations converge, leading to an eventual convergence of actions, comparable to John Dewey’s “cooperative intelligence”. They usually don’t act for the good of the whole crowd, but act according to what’s best for themselves (see Surowiecki 2004). This includes behavior that is judged highly irrational or short-sighted from an outside perspective (see e.g., Simon 1996). Nevertheless, humans can coordinate their actions and achieve complex goals that would not be achievable by individuals (like writing a high-quality encyclopedia or finding a relevant piece of information from billions of web-sites<sup>1</sup>).

From a collective intelligence point of view, cognitive problems (as often appear in a Crowdsourcing context) are even harder to solve than coordination or cooperation problems, because they are often very difficult to centrally organize for a group solution. The solution approach to such

problems is usually emergent and contains almost no formal structuring (see, e.g., *ultimatum* or *common good* games).

### Organizations and Open Innovation

We will use an organizational (more precisely, Open Innovation) context for the basis of the simulation to define more clearly the environment within which our agents are interacting. In this context, Crowdsourcing is often seen as innovation-seeking: Organizations create, acquire, and integrate diverse knowledge and skills required to develop complex innovative technologies. Since knowledge is available from the outside (see, e.g., Chesbrough 2003) the organizations may benefit from leveraging external knowledge. Crowdsourcing is an increasingly popular approach for doing that. Not only are seekers and solvers involved, but also a wide variety of other, intermediate organizations. The acquired capabilities are combined and re-combined without centralized, detailed managerial guidance – again showing a high degree of self-organization. Joel West, one of the first researchers to address “Open Innovation”, defined it as “using the market rather than internal hierarchies to source and commercialize innovations.”

### Other Important Insights

Two important underlying concepts in Crowdsourcing are *private information* and *tacit knowledge*, both emphasizing the “stickiness” of information (information used in technical problem solving is often costly to acquire, transfer, and use in a new location, see von Hippel 1994). An important prerequisite for the success of Crowdsourcing is to maintain the *diversity* of the crowd members’ knowledge and skills throughout the process and to avoid *groupthink*.

**Private information.** (von Hayek 1945) observed that humans possess a special type of local information that is hard to aggregate. Due to such “private information”, nearly every individual “has some advantage over all others because he possesses unique information of which beneficial use might be made.” Crowdsourcing brings together and motivates individuals to collaborate and produce innovation or solve problems based on this private information.

**Tacit knowledge.** Michael Polanyi coined the term in the 1950s using “riding a bicycle” as an example of something humans are able to do “without quite knowing how”. In a Crowdsourcing context, three phenomena can be observed: Communication between different experts may lead to new developments, which implies that each expert’s knowledge is not “tacit”. What Crowdsourcing does is establish new correlations between pieces of knowledge acquired by individuals. A second phenomenon is knowledge that is not “owned” by an individual, or *collective tacit knowledge*. It is neither clear how it can be described nor how it is acquired as a “good of the group”. An example of such collective tacit knowledge under constant change is human natural language. Crowdsourcing not only generates, but potentially also maintains collective tacit knowledge. The third phenomenon derives from the observation that an individual may have knowledge but might not be able to communicate it in a formalized way (“riding a bicycle”). Several studies suggest

<sup>1</sup> Google’s Pagerank algorithm crowdsources a great deal of collective human intelligence to rate the importance of pages by linking to them.

that especially such tacit knowledge and knowledge of technique are best conveyed through collaboration (Lee and Bozeman 2005), as happens in Crowdsourcing. In summary, Crowdsourcing helps locate and productively use these different types of tacit knowledge that cannot be found by the most sophisticated search engines due to its “tacitness”.

The combination of private information and tacit knowledge explains why “irrational” individuals can produce rational outputs: “Rationality” requires some basic assumptions plus logic. In order to apply logic, the assumptions need to be stated in one or the other form of a proposition. Tacit knowledge can be rational and logical, but cannot be stated or codified. Therefore, individual behavior may appear irrational to outsiders. Due to the collective intelligence unearthed during a Crowdsourcing interaction, combining private information (tacit or not) to a solution for a complex problem, the seemingly irrational becomes rational and productive. This implies, however, that optimal group outcomes are hard to achieve because the barrier of perceived individual irrationality needs to be overcome.

#### Expertise, diversity, independence and groupthink.

(Page 2008) found evidence for the advantage of diversity in groups performing complex tasks by running agent-based simulations. His surprising insight was that groups with diverse agents almost always performed better than groups consisting only of expert agents. Herbert Simon (1996) used the term “docile” for individuals who tend to accept information and advice from the social groups to which they belong. He theorized that these individuals have great advantage in fitness over those who are not docile. And it is not easy to stay independent of a social environment since learning is a social process. One can therefore say that although the members of a crowd should show a certain level of docility by e.g., building on previous solutions (if public), the group as a whole should maintain a high diversity of skills and private information. On the other hand, the crowd should avoid “groupthink”. Irving Janis defined the term in the 1970s as follows, based on William H. Whyte’s original 1952 definition: “A mode of thinking that people engage in when they are deeply involved in a cohesive in-group, when the members’ strivings for unanimity override their motivation to realistically appraise alternative courses of action.” On a closed Crowdsourcing platform, where solvers cannot see other solvers’ solutions (which is often the case when monetary premiums are involved) the likelihood of groupthink is clearly much smaller. (Surowiecki 2004) identifies stock bubbles and crashes as famous examples where all of the factors that make crowds smart (independence, diversity, and personal opinion) disappear.

Synthesizing the above sections, once a problem has been formalized and established methodologies exist for its solution (and it is well understood what a solution is), a group of experts may obtain the “correct” solution. However, as long as these methodologies do not exist, no “objective” formulation of the problem has been found and/or evaluation criteria for solutions are not completely formalized, diversity may beat expertise (see discussion and further references in Buecheler et al. 2010). Restricting the group of problem solvers to experts overlooks the fact that this happens at the price of groupthink (acquiring expertise usually includes a certain

level of docility). Maintaining diversity therefore inhibits the very occurrence of groupthink.

## Crowdsourcing in a Nutshell

This section briefly describes the Crowdsourcing process used for our simulator and introduces nomenclature in *italics*. (Muhdi et al. 2010) gives a more detailed description of the activities involved.

- 1. Deliberation:** A *seeker* (an organization<sup>2</sup> or individual) decides to use external sources to generate ideas or solve a specific problem.
- 2. Preparation:** The seeker often chooses an intermediary (information broker), i.e. a website that brings together the seeker and the *crowd* (group of *solvers*) and usually enters into a contract with this information broker.
- 3. Execution:** The seeker posts a *problem* on the Internet. The solvers self-organize and self-select which of all posted problems they would like to work on. The seeker might or might not interact with the solvers during this phase.
- 4. Assessment:** After the execution phase (or perhaps in parallel), the submitted ideas are clustered, rated, and the best idea is rewarded. In our simulator, one to five ideas (the *winning solutions*) receive the *prize premium* (if any).
- 5. Post-processing:** The collected ideas are incorporated into the seeking organization and “side effects” (e.g., creative spillovers useful elsewhere) are managed (if any).

## Complexity and Focus Trade-off in MAS

This simulator attempts to optimize the balance between complexity and focus.

Many simulators for understanding social behavior are based on mathematical models using partial differential equations (PDEs). Multi-agent system simulations have been shown to have certain advantages over these models when simulating large groups of agents. This is also true for a Crowdsourcing model: PDEs cannot handle diverse populations efficiently. Diversity requires particle or agent based models for two reasons: PDEs are increasingly difficult to solve if the number of variables increases and they cannot handle discretization (you either have at least one individual knowing about XY in a group, or this knowledge is not there at all. There is never half of an expert) or stochastic fluctuations as appear in Crowdsourcing. Our simulator is built on modules that incorporate empirically shown parameters in a Crowdsourcing scenario. Thus, it intrinsically simplifies and omits certain properties. However, too much simplification can make a model unnecessarily unrealistic and uninteresting. The simulator includes an adequate level of complexity by incorporating several parameters, while focusing on the parameters that give the “simplest explanation” for the emerging phenomena.

<sup>2</sup> We use “seeker” for any kind of individual or organization (including companies and universities). Science is, in many cases, trying to find inventions or seek evidence for observed/hypothesized phenomena. The processes and paradigms, however, are similar to a large extent.

## Parameters Used for the Simulator

In this section, we show parameters allocated to “seekers”, to the “problem” and finally to “solvers”. In addition, we list some important global parameters used. See Figure 1 for an overview of the most important parameters and their interdependencies. For a detailed description of the parameter representation and spaces please contact the corresponding author.

### Seeker Parameters

The seeker parameters model environmental and internal variables for the seeking organization (e.g., a company or university).

**Degree of revealing and Intellectual Property (IP) regime.** Depending on the strictness of the IP (or “appropriability”) regime (Teece 1986) organizations, especially firms, adopt different formal and informal methods (patents, trademarks, copyright, time-to-market, trade secrets) to adjust their degree of openness. This influences the potential success of the problem in Crowdsourcing: the trade-off between openness to provide maximum information to the solvers while protecting own intellectual property needs to be found. (Henkel 2006; von Hippel and von Krogh 2003) show that openness is not automatically a disadvantage. IBM (according to Kazman and Chen 2009 the most patent-productive company in the world) began making more money from crowdsourced services than from all its patent-protected intellectual property (Benkler 2006). (Dahlander and Gann 2010) has further elaborated on this trade-off in an excellent literature review on Open Innovation while (Lakhani et al. 2006) has shown the importance of openness in a Crowdsourcing context. The difficulties of protecting IP in Crowdsourcing have not yet been resolved.

University researchers tend to be more open (see, e.g., David 2003) but since the introduction of the Bayh-Dole Act in the US in 1980 and similar legislation in other countries, there has been a trend towards more “closed” research. In this context, (Heller and Eisenberg 1998) popularized and discussed the phrase “tragedy of the anticommons”.

**Level of NIH.** (Katz and Allen 2007) described the effect of the “Not-Invented-Here” (NIH) syndrome, the “tendency of a project group of stable composition to believe it possesses a monopoly of knowledge of its field, which leads it to reject new ideas from outsiders to the likely detriment of its performance”, on R&D project groups. This syndrome is clearly relevant in a Crowdsourcing context and it has been shown that a lower level of NIH supports successful internal and external solution development (Brown and Eisenhardt 1995).

**Absorptive capacity.** The term defined in (Cohen and Levinthal 1990) refers to the ability of a seeker to recognize the value of new, external information, assimilate it, and apply it to commercial ends. This parameter is assigned to the seeking agents and will rise over time, when the seeker climbs the Crowdsourcing learning curve and accumulates prior related knowledge (see also Brown and Eisenhardt 1995 for a

discussion). The basic assumption for both NIH and absorptive capacity is that the individuals at the seekers’ interfaces and the crowd co-evolve by exogenous influences and endogenous self-organization (Mitleton-Kelly 2003).

**Historical success rate.** This parameter is used to modify the “Level of NIH” and “Absorptive Capacity” parameters over time. In essence, it shows how far the seeker is on the Crowdsourcing learning curve.

**Crowdsourcing success.** This parameter can only be set as a dependent/output variable. It estimates the success of the product or patent based on the solution/idea gained in the Crowdsourcing process (not incorporating side effects). (Howe 2008) found that an InnoCentive.com company’s average earnings from a successful solution are twenty times the fee paid to a solver. The parameter is influenced by the solution quality, the level of NIH and the absorptive capacity of the seeker. A side remark: The measurement of Crowdsourcing success varies widely between different types of organizations or businesses. Examples are business measures related to finances, employees’ motivation, new product revenue, spending in R&D, number of patents, time to market, and combinations thereof. The build-up of absorptive capacity could in fact already be a goal and measure of success for an organization.

### Problem Parameters

**Problem value – intrinsic.** Several Crowdsourcing interactions do not only target crowds looking for additional income, but also solvers working for intrinsic motivation. Open source developers, for example, show very different motivating factors (see intrinsic motivation factors, below).

**Problem value – monetary.** Most Crowdsourcing platforms assign a prize premium to a problem. Although on many platforms there is no limit, the seeker may divide the premium from zero up to five “winning” solutions in our simulator, in order to constrain simulation complexity (typical is 0 to 10).

**Problem field.** Every posted problem is assigned a primary and (optional) secondary field (or scientific discipline). Examples are “molecular biology” or “organization science”. For our simulator, we used the fields selectable at Innocentive.com (currently the largest Crowdsourcing platform). Solvers do not only work successfully on problems from their respective fields: (Lakhani et al. 2006) found the odds of a solver’s success increased in fields in which they had no formal expertise, confirming a network theory insight from (Granovetter 1973): The most efficient networks are those that link to the broadest range of information,

knowledge, and experience. (Howe 2008) summarizes another important insight from Lakhani’s paper:

A full 75 percent of successful solvers already knew the solution to the problem. The solutions to the problems in the study – many of which [...] had stumped the best corporate scientists in the world after years of effort – didn’t require a breakthrough, or additional brainpower,

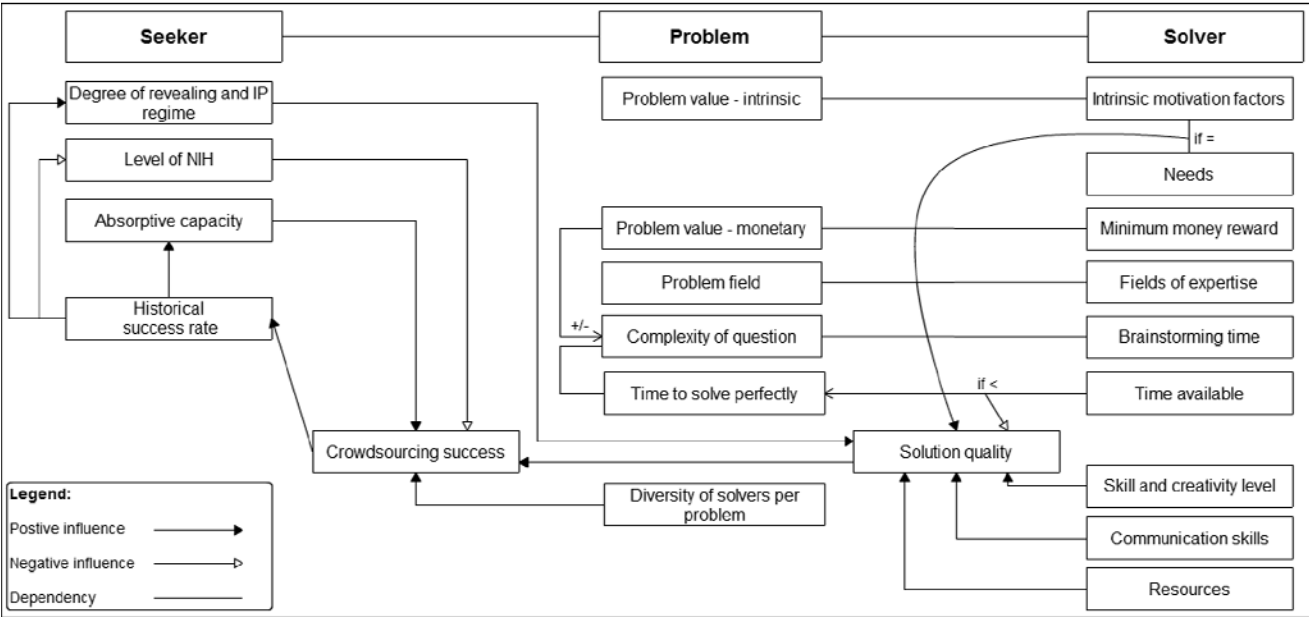

Figure 1 - Overview of simulation parameters described in this paper and their interactions

or a more talented scientist's attention; they just needed a diverse enough set of minds to have a go at them.

**Complexity of question.** This parameter indicates how complex a question is and the time investment needed by a solver. It also influences how well a solver can understand the question and how much time the solver needs to brainstorm a potential solution. (Benkler 2006) defines the benefits of dividing a problem to decrease its complexity as the “property of a project that describes the extent to which it can be broken down into smaller [...] modules that can be independently produced before they are assembled into a whole. [...] While creative capacity and judgment are universally distributed in a population, available time and attention are not.” (Schenk and Guittard 2009) differentiates between routine tasks Crowdsourcing and complex tasks Crowdsourcing: “Routine tasks Crowdsourcing seeks a number of complementary contributions necessary for the construction of data and information bases. Complex tasks Crowdsourcing follows a diametrically opposed pattern [...]”

**Time to solve perfectly.** This parameter is used in the simulation to determine the time a solver would need to solve a problem perfectly. However, it is not known to seekers or solvers, but only to the simulator.

**Diversity of solvers per problem.** This parameter combines the diversity of solvers (backgrounds, age, etc.) that worked on the solved problem. A higher diversity grade will generate a better winning solution (see “State of the art”).

**Solver Parameters**

The solver parameters include parameters for the members of the crowd and the submitted solutions (if any).

In a Crowdsourcing scenario, pedigree, race, gender, age, level of expertise and similar are not relevant (on most platforms, the participants are anonymous to others). Such typical moderating variables in team and sociological studies are not relevant to Crowdsourcing success.

**Intrinsic motivation factors.**

Successful Crowdsourcing involves satisfying very basic needs. (Bartl 2010) writes:

Drawing on a rich body of motivation research relevant motives are curiosity, self efficacy, skill development, information seeking, intrinsic playful task, recognition, altruism and community support, make friends, personal need/dissatisfaction or compensation and monetary rewards.

**Solution quality.** In the simulator, solution quality is influenced by the solver’s skill level, communication skills, resources (e.g., laboratory supplies), time available and the seeker’s degree of revealing (accuracy and background information in problem description). Examples of quality are, e.g., enhanced technical performance, lower cost, good reliability, contribution to the research question or uniqueness. Seekers judging the solutions are regarded as “satisficers” (Simon 1996).

**Fields of expertise.** Every agent has a set of skills in one or more fields of expertise, influencing both problem selection and solution success potential. However, the solver does not necessarily need to have a field of expertise that matches the problem field exactly (see explanation of problem field, above). A solver with high general skill and creativity levels is able to pick problems outside his or her fields of expertise. The “skills” parameter includes the solvers’ private information, as defined by von Hayek.

**Brainstorming time.** Indicates the total time a potential solver takes to understand and respond to a posted problem.

**Time available.** Analogous to computer programs like SETI@home that use collective CPU spare cycles for supercomputing and hence leverage the power of the network, crowd members generally contribute to posted problems during their “spare cycles”, their downtime and energy not claimed by work or family obligations (Howe 2008), hence every simulator agent has a defined time available.

**Skill and creativity level.** This parameter shows a solver’s ability to solve a problem well. With a skill and creativity level above a certain threshold, the solver is also able to select and work on problems outside the field of expertise.

**Communication skills.** A solver with a higher (written) communication skill will have a greater chance of winning since she or he is better able to describe the idea/solution. In addition, this parameter positively affects the communication with other crowd members (if enabled).

**Resources.** Comprises all relevant resources (infrastructure, tools etc.) except for time and money that an agent has at hand and that are relevant for the chosen problem.

**Needs.** An agent with a need related to a field or type of problem more likely picks that problem and, if working on the problem successfully (resources, skills, time etc.), has a higher likelihood of delivering a superior solution. (Putnam 2000) and several others found that social innovation often occurs in response to social needs and that market pull (identifying and understanding users’ needs) is substantially more important to product success than technology push.

#### Global Parameters and Further Comments

For this simulator version, we assume a “closed” Crowdsourcing system, i.e., members of the crowd cannot see solutions already submitted by other members.

**Acquaintances.** The set of agents (seekers and solvers) starts with a set of agents the agent in question knows from “earlier times”. With every Crowdsourcing interaction, the set grows. “Old acquaintances” might be forgotten over time.

**Goal.** Every agent has a “goal”. For seekers, this is usually “maximization of Crowdsourcing success”. Solvers have all kinds of goals, including maximizing an intrinsic motivation factor or monetary income.

**Direct communication.** A global parameter that toggles whether seekers and solvers can directly communicate after the solver has picked a problem. The parameter simulates anonymity that is ensured on many Crowdsourcing platforms. A solution delivered by a solver communicating with the seeker increases the chance of winning (better understanding of the problem and its circumstances and hence higher quality solution). Communication with other crowd members decreases the solution quality due to reduced independence and diversity.

Whenever a relation is needed between parameters and there is no empirical evidence available, we use a “power law” according to (Mandelbrot and Hudson 2008) including the special case of the “1:10:89” rule: for every 100 people on a given site, 1 will create something, 10 will vote on what he or she created; the remaining 89 will consume the creation. “Super contributors”, between 1% and 2.5% of all solvers, depending on the platform, are usually responsible for a large share of crowdsourced data and knowledge collections.

## Simulator Set-up

(Wooldridge 2008) writes: “the steady move away from machine-oriented views of programming toward concepts and metaphors that more closely reflect the way in which we ourselves understand the world” is an ongoing trend. Further, he says agent-based solutions are appropriate when “the environment is open, or at least highly dynamic, uncertain or complex” and “agents are a natural metaphor”. Our highly scalable simulator conforms to these prerequisites.

### The Jade Framework Used for the Simulator

Jade (“Java Agent DEvelopment Framework”) was developed in 2000 as “an enabling technology, a middleware for the development and run-time execution of peer-to-peer applications which are based on the agents paradigm” (Bellifemine et al. 2003).

Agents, as defined for this kind of multi-agent programming, are autonomous, proactive and social peers that are provided interoperation capabilities by the framework. Jade provides the programmer with the capabilities to create agents that are loosely coupled and come with a fully enabled asynchronous messaging system between all actors.

Further points for selecting Jade over other frameworks were its interoperability by being compliant with the FIPA (“Foundation for Intelligent Physical Agents,”) specifications, its open source license, the large programmer community, the amount of documentation available and the great scalability.

### Design

The simulator models both seekers and solvers involved in a typical Crowdsourcing context. The current version does not include the potential intermediary as an additional type of agent: The Jade Framework provides a “Yellow Pages” agent that is used as a “broker” and matches solvers with problems.

Solvers are able to search the yellow pages as a directory for problems matching their given skills. The seeker and solver can then start communicating with each other directly, if allowed.

After toggling global conditions, users define value ranges for the active parameters and choose which variable is the dependent variable for this simulation cycle. The user may also choose to load own data (the ranges are then discretized by the software) or select from a given set of probability distributions. Figure 2 shows a screenshot. The output variables can be aggregated over several cycles and used for sensitivity analyses and other (e.g., statistical) evaluations. For technical and implementation details please contact the second author.

## Discussion and use cases

The simulator's robustness is currently being increased by incorporating data from Crowdsourcing in two domains: Corporate R&D and basic science as conducted at research universities. To this end, we will use data collected in the studies presented in (Lakhani et al. 2006) and (Buecheler et al. 2010). In addition, we have just started a collaboration with the largest Swiss Open Innovation site, "atizo.com" to gather more data from daily interactions. As the following three use cases show, the simulation is benefiting both researchers and practitioners:

### Use Case 1: Scientific Inquiry: Analogies to Biology

Scientists may (and will) use the simulator for confirming observations from biology in a complex network of irrational human agents. E.g., we hypothesize that solution development in open Crowdsourcing systems (as observed, e.g., in Mathwork's Matlab programming contests: Gulley 2004) resemble the developments of evolution in the sense that phases of regular, gradual evolution alternate with more punctuated sequences and stasis. (For a critical discussion see e.g., Smith 1988). In addition to these varying speeds, we expect to observe other phenomena like mass extinctions, co-evolution, and growing complexity of the behavior patterns and strategies that survive. (Emmeche 1994), (Lindgren 1992).

### Use Case 2: Scientific Inquiry: Crowdsourcing Dynamics

The simulator helps achieve three goals that (Axelrod 1997) has compiled: 1. Explore/describe: find basic system dynamics and qualitative interdependencies as well as quantitative correlations between (Crowdsourcing) parameters. For example, we hypothesize that the functions for resources, needs and fields of expertise have to be correlated to best approximate empirical outcomes and additionally communication skills need to be correlated with acquaintances. 2. Confirm/explain: use the simulator to explain agents' complex behavior and verify or falsify

assumptions while constantly ameliorating the simulator through empirical data. 3. Forecast/predict: consider complicated input variables and influencing factors to generate predictions, heuristics or narrower solution spaces.

### Use Case 3: Practical Use

Practitioners from the private sector (as well as scientists wishing to use Crowdsourcing as a tool, see Buecheler et al. 2010) may use the simulator for testing Crowdsourcing scenarios, parameter sensitivities and the optimal setting for their Crowdsourcing plans. Crowdsourcing consultancies, currently being founded all over the world, can use the simulator to test real-life settings. This not only helps increase effectiveness, but also communicates the value of Crowdsourcing and supports increasing the openness of the seeking organization.

## Conclusions

In contrast to simple existing models, the simulator allows the user to predict what is needed to achieve optimal Crowdsourcing results with the given resources, incorporating a large set of potential influences. In addition, the modular and extensible way the simulator is built enables the user to increase the accuracy and predictive power when scientists gain new empirical insights.

### Contributions by Authors

Most of the theoretical contributions were written by the first, third and fourth authors. The simulator design and details are mainly contributed by the second author.

## Abstract

Populations of individuals exist in a wide range of sizes, from billions of microorganisms to fewer than ten individuals in some critically endangered species. In any evolutionary system, there is significant evolutionary pressure to evolve sequences that are both fit and robust; at high mutation rates, individuals with greater mutational robustness can outcompete those with higher fitness, a concept that has been referred to as survival-of-the-flattest. Previous studies have not found a relationship between population size and the mutation rate that can be tolerated before fitter individuals are outcompeted by those that have a greater mutational robustness. However, using a genetic algorithm with a simple two-peak fitness landscape, we show that the mutation rates at which the high, narrow peak and the lower, broader peak are lost for increasing population sizes can be approximated by exponential functions. In addition, there is evidence for a continuum of mutation rates representing a transition from survival-of-the-fittest to survival-of-the-flattest and subsequently to the error catastrophe. The effect of population size on the critical mutation rate is shown to be particularly noticeable in small populations. This provides new insight into the factors that can affect survival-of-the-flattest in small populations, and has implications for populations under threat of local extinction.

## Introduction

Biological population sizes can range from small numbers of individuals to very large numbers of individuals. For example, RNA viruses can reach population sizes of around  $10^{10}$  in a short amount of time (Comas et al., 2005), whereas some animal species may exist in populations consisting of only hundreds or even fewer than ten individuals in some critically endangered species saved on the brink of extinction. A population of genomes constantly evolves through the processes of mutation, recombination (in sexual reproduction), selection and genetic drift (Hartl and Clark, 2007). Population dynamics can be modelled *in silico* using genetic algorithms, in which populations of sequences are allowed to undergo mutation, recombination and selection at specified rates; studies can be done in a controlled environment within time-frames not possible in many natural biological systems, producing results that are comparable both to theory and to experimental results in microorganisms.

In any evolutionary system, including genetic algorithms and natural biological systems, there is significant evolutionary pressure to evolve sequences that are both fit and robust (Jones and Soule, 2006). Robustness is defined as the average effect of a specified perturbation (such as a new mutation) on the fitness of a specified genotype (Masel and Trotter, 2010). The more robust a genotype, the smaller the effect of mutation on fitness; in systems with high levels of mutation, robustness can reduce the negative effects of deleterious mutation. Smaller populations are more susceptible to loss of fitness through random genetic drift (Comas et al., 2005; Hartl and Clark, 2007). Therefore it is expected that population size should influence the size of mutation rate that can be tolerated before fitter individuals are outcompeted by those with a greater mutational robustness.

## Mutational Robustness and Survival-of-the-flattest

The concept of a fitness landscape was introduced by Wright (1932) and later combined with the notion of sequence space by Eigen and Schuster (1979). Each sequence in sequence space has a fitness value, which represents its relative replication capacity (Domingo and Wain-Hobson, 2009). Fitness landscapes are sometimes considered to resemble mountain ranges, with the fittest sequences at the peaks. However, the concept requires a more careful interpretation in high dimensional sequence spaces with low alphabet size, such as nucleic acids, which have an alphabet size of four (in that they are sequences consisting of four possible units, A, C, G and T). For example, the space of  $N$ -length binary sequences is an  $N$ -dimensional hypercube rather than a 3-dimensional Euclidean geometry, and can only be represented as such by use of a reductive transform between the two spaces. Exploration of sequence space is done through evolution by mutation, recombination and selection in accordance to the fitness landscape. Selection increases the frequencies of the fittest sequences, while mutation introduces variation, often at a cost to individual fitness. The balance between these two forces is referred to as the mutation-selection balance (Kimura and Maruyama, 1966; Bull et al., 2005). A popula-

tion in mutation-selection balance will tend to cluster around the fitness peaks and form what is known as a quasispecies (Eigen and Schuster, 1979; Bull et al., 2005; Nowak, 2006).

In a landscape with a single fitness peak, a quasispecies is able to maintain its position surrounding the top of the peak so long as the mutation rate does not exceed a particular rate known as the *error threshold*. Above this threshold, there is an *error catastrophe* and the population delocalizes across sequence space (Tannenbaum and Shakhnovich, 2004; Bull, 2005; Nowak, 2006; Takeuchi and Hogeweg, 2007; Domingo and Wain-Hobson, 2009; Schuster, 2009; Tejero et al., 2011).

The concept of error threshold was introduced in Eigen et al. (1988) and later in Nowak and Schuster (1989) based on the quasispecies equation:

$$\dot{x}_i = \sum_{j=1}^m x_j f_j q_{ji} - \phi x_i$$

Here,  $x_i$  is the frequency of genotype number  $i$ , where  $i \in [1, \dots, \alpha^n]$ ,  $\alpha$  is the alphabet size,  $n$  is the length of sequences,  $\sum x_i = 1$ ,  $f_j$  is fitness (selection),  $\phi = \sum x_i f_i$  is the average fitness, and  $q_{ji}$  is a transition probability (mutation). The derivative in time is denoted  $\dot{x}$ , and there are  $m$  genetic sequences.

Selection and mutation provide two forces (or pressures) on the population, and they can be combined into one matrix ( $w_{ji} = f_j q_{ji}$ ) (see Nowak (2006), p. 35). Selection draws the population closer to the highest fitness, while mutation is usually assumed to have deleterious effect due to which the population drifts away from the highest fitness. Generally, the population converges to a stable (equilibrium) state that is defined by an eigenvector of the mutation-selection matrix ( $w_{ji}$ ). This eigenvector corresponds to the largest eigenvalue of ( $w_{ji}$ ), which is the average fitness  $\phi$ .

The idea of an error threshold is based on the existence of a mutation-selection balance when the effect of mutation does not exceed that of the selection pressure. The corresponding value of the mutation rate is referred to as the error threshold, and it is the maximal mutation rate that allows a population to stay centred ‘around’ the fitness peak.

However, in landscapes with more than one peak, there may also be one (or more) *critical mutation rates* at which the population loses its ability to localize to fitter peaks, while potentially retaining its ability to remain on lower, flatter peaks (Wilke et al., 2001; Tannenbaum and Shakhnovich, 2004; Comas et al., 2005; Wilke, 2005). This represents a phase transition from survival-of-the-fittest to survival of those individuals with greater mutational robustness, a concept referred to as survival-of-the-flattest (Wilke et al., 2001; Bull et al., 2005; Comas et al., 2005; Wilke, 2005; Sanjuán et al., 2007; Sardanyés et al., 2008; Tejero et al., 2011). This concept is based on the idea that at low mutation rates, selection favours individuals in a quasispecies that reside at peaks

with higher fitness, even if the peaks are steep and narrow, due to the rarity of mutations that push individuals off the peaks (Lenski et al., 2006). In contrast, at high mutation rates, selection favours individuals that reside at peaks less likely to result in off-peak mutations: individuals located in flatter regions of the fitness landscape are less likely to suffer large reductions in fitness compared with those that may be initially fitter but reside in parts of the landscape with steeper peaks. Individuals that are part of a neutral network (Kimura, 1983), in that they are surrounded by other individuals with equivalent fitness, are said to be mutationally robust (Bull et al., 2005; Bornberg-Bauer and Kramer, 2010; Wilke, 2001a; Wilke, 2001b); their fitness will be less sensitive to mutation than individuals that are not well connected.

Survival-of-the-flattest has been observed in digital organisms (Wilke et al., 2001; Sardanyés et al., 2008), theoretically (Wilke, 2001a; Sardanyés et al., 2008), in simulated RNA evolution (Wilke, 2001b), and in RNA viruses (Sanjuán et al., 2007). In addition, evolution of mutational robustness has been observed in simulated RNA evolution (van Nimwegan et al., 1999) and in laboratory protein evolution experiments (Bloom et al., 2007). Both van Nimwegan et al. (1999) and Bloom et al. (2007) place an emphasis on the degree of polymorphism in the population, suggesting that highly polymorphic populations are more likely to spread across many nodes of a neutral network (each corresponding to a genotype), concentrating at highly connected parts; individuals at highly connected nodes have greater robustness to mutation, which they pass on to the next generation. Robustness will evolve in any population where the product of the population size and frequency of mutation per sequence per generation is sufficiently large ( $>1$ ). Krakauer and Plotkin (2002) refer to flat landscapes as redundant, and steeper landscapes as antiredundant. They suggest that both in theory and in individual-based stochastic simulations, redundancy increases the mean fitness in small populations as it masks mutations that arise due to mutational drift. However, large populations are less affected by drift, and so are more able to occupy high-fitness peaks in sharp landscapes.

Wilke (2001b) ran simulations with population sizes as low as 100 and noted “that for very small populations, the predictive value of the differential equation approach diminishes”. Later Wilke noted that his results agreed with Comas et al. (2005) in finding “that population size played only a minor role in determining the position of the critical mutation rate” (Wilke, 2005), within the context of their experiments. Comas et al. used population sizes as low as 250 and concluded “that the critical mutation rate was independent of population size” (Comas et al., 2005) despite the fact that there did appear to be some correlation for certain cases.

Jones and Soule (2006) determined that the role of genetic robustness in evolution differs significantly depending on whether it is a generational or steady state genetic algorithm that is being used. In a steady state algorithm, only

a few individuals are replaced at a time, as opposed to a generational algorithm which replaces the entire population at once. Many studies that have confirmed the notion of survival-of-the-fittest have used generational models, such as Wilke et al.'s (2001) evolution of digital organisms in Avida, and Krakauer and Plotkin's (2002) study of redundancy and antiredundancy (Jones and Soule, 2006). Jones and Soule suggest that for evolutionary dynamics experiments, the class of algorithm used can have a significant effect on the observed outcome. They point to steady state algorithms as being of particular interest to the artificial life community, as natural evolution resembles the action of a steady-state-like algorithm: evolution in biological systems does not usually follow the generational approach of evolving every individual in the population synchronously.

However, the problem with steady state algorithms is that they typically allow individuals to survive on fitness peaks indefinitely. This is not a realistic property when modelling evolutionary dynamics. A preferable approach is to use a generational genetic algorithm which retains the key features of steady state evolution: fitness rank-based selection and a degree of asynchronicity. It should be noted that fitness in this sense refers to a score assigned to each individual based on a given fitness function, as opposed to the biological definition of fitness as a measure of replication rate; the exact fitness values used are unimportant as it is relative fitness that determines which individuals are selected. Rank-based selection (the assignment of reproductive fitness rates according to fitness score rank) overcomes the scaling problems of fitness score proportional selection (the assignment of reproductive fitness rates in proportion to fitness score), so creating a general model from a specific fitness score landscape such as that in figure 1, while retaining the key property that sequences with higher fitness scores have (probabilistically) more offspring than those with lower scores. This approach also allows for the existence of a critical mutation rate: with a standard steady state algorithm, always retaining the fittest individual prevents the population from ever losing the highest current peak.

### Simulation Model

An individual sequence consists of a string of characters drawn from an alphabet of size 4 (which can be thought of as, for example, A/C/G/T or 0/1/2/3) with a fixed length of 30. In each step of the algorithm, three individual sequences are selected at random from the population. Two of the three selected individuals are chosen as parents in a crossover which replaces the third individual with the resulting child. The child is then subject to one round of point mutation (to a *different* base) at a given per-base mutation rate. The individual to be replaced is decided each time based on the fitnesses of the three selected individuals: there is an equally small chance of either of the two fittest of the three being replaced (25%), and a larger chance of replacing the

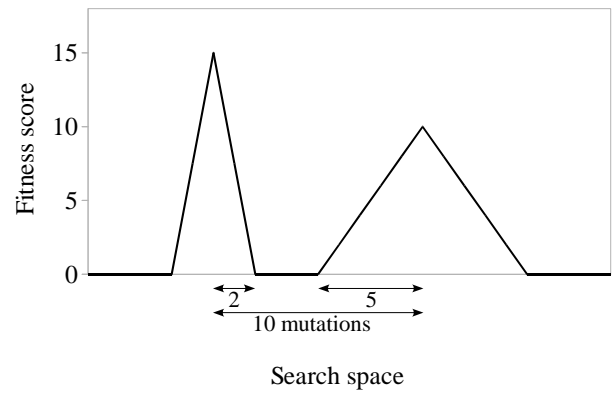

Figure 1: Two-peak fitness landscape, with one narrow peak of high fitness (peak 0), and one broader, flatter peak of lower fitness (peak 1).

least fit (50%). This process continues until each individual in the population has been chosen exactly once; this represents one generation, and ensures that there is no chance of any individual avoiding being chosen and so remaining static in the landscape. The fitness of each individual sequence is evaluated based on a two-peak fitness landscape with one narrow peak of high fitness (peak 0), and a broader, flatter peak with lower fitness (peak 1) (figure 1). Peak 0 has a maximum fitness score of 15 and a radius (Hamming distance from top-of-peak to zero fitness score) of 2; peak 1 has a maximum fitness score of 10 and a radius of 5, with its top chosen as an arbitrary point (fixed throughout evolution) with a Hamming distance of 10 from the top of peak 0. Individuals are allowed to move anywhere on the slopes, or in between the peaks. This is a simple landscape in which survival-of-the-fittest can occur. The effect of mutation on fitness is smaller within peak 1 than within peak 0; individuals located on peak 1 will have higher mutational robustness compared with those located on peak 0.

Following the experimental procedure designed by Wilke et al. (2001) (and used by Comas et al., 2005) we initialized half of the population of sequences to be on top of the high, narrow peak, and the other half to be on top of the lower, flatter peak. This procedure prevents initialization bias between peaks. The simulation was run for 10,000 generations, and the number of generations it took to first lose each peak was recorded (where a peak was considered to be lost when there were no individuals present anywhere in its range). If a peak was never lost within the 10,000 generations, a value of -1 was recorded. A range of per-base mutation rates was tested for a range of population sizes. The simulation was run 2,000 times for each combination of mutation rate and population size. The mutation rate by which 95% of the runs had lost each peak was recorded, where a peak was considered to have not ever been lost only if there were individuals remaining on it at the end of the 10,000 generations.

Table 1: Mutation rate  $\mu_0$  by which 95% of runs lost peak 0.

## Results

The results (figure 2, and tables 1 and 2) show that population size affects the size of mutation rate required for the predominant outcome of the runs to shift from survival-of-the-fittest to survival-of-the-flattest, and that this is particularly noticeable in populations with 100 individuals or less. Similarly, the size of mutation rate required for approximately 95% of the runs to have lost both peaks also has a dependence on population size. The results of the simulation can be approximated by a simple exponential function:  $y = A - B m^C$  for some values of the parameters  $A$ ,  $B$  and  $C$ , where  $m$  is population size. However, they are more closely fitted by a stretched exponential function:  $y = A - B * e^{-((m/C)^D)}$ .

As opposed to there being instantaneous transitions from survival-of-the-fittest to survival-of-the-flattest and to the error catastrophe, at discrete mutation rates, there appear to be gradual transitions in which there are shifts in tendency from the first to the second, and from the second to the third. The mutation rate corresponding to 95% of the runs having lost the high, narrow peak (peak 0) within 10,000 generations marks a point at which the former transition (from survival-of-the-fittest to survival-of-the-flattest) is essentially complete. This can be considered as a critical mutation rate. For a population of 100 individuals, this is at a per-base mutation rate of approximately 1.08% (table 1). Figure 3(a) shows the number of generations taken to lose each peak at this mutation rate, for each of the 2,000 runs with population size 100. Just 52% of these runs lost peak 1 within the dura-

Figure 2: The results of the simulation for both peak 0 (high, narrow peak) and peak 1 (lower, flatter peak) can be approximated by an exponential function, where  $y = A - B * e^{-((m/C)^D)}$  (with  $m$  being population size). The parameters obtained by curve-fitting using a least squares method were, for peak 0:  $A = 1.221\%$ ,  $B = 7.001\%$ ,  $C = 1.440$ ,  $D = 0.3250$ , and for peak 1:  $A = 2.184\%$ ,  $B = 5.438\%$ ,  $C = 7.721$ ,  $D = 0.3978$ .

Table 2: Mutation rate  $\mu_1$  by which 95% of runs lost peak 1.

tion of the simulation (compared to 95% for peak 0). At this mutation rate, early loss of peak 0 appears to be a condition for survival-of-the-flattest. Loss of peak 0 is then followed by one of two events: either peak 1 is lost relatively quickly (within 200 generations) or it is maintained for the duration of the simulation. The fate of the population after loss of peak 0 is therefore dependent on whether or not it is able to quickly converge on peak 1. Figure 3(a) shows (at this mutation rate) that when peak 0 is not lost early, the number of generations taken to lose peak 0 is distributed approximately evenly up to 10,000 generations.

The mutation rate corresponding to 95% of the runs having lost the lower, flatter peak (peak 1) within 10,000 generations marks a point at which the latter transition (from survival-of-the-flattest to the error catastrophe) is essentially complete. This can be considered as another critical mutation rate (or the error threshold). For a population of 100 individuals, this is at a per-base mutation rate of approximately 1.85% (table 2). Figure 3(b) shows the number of generations taken to lose each peak at this mutation rate, for each of the 2,000 runs with population size 100. It is an apparent reversal of figure 3(a) but with 100% of the runs having lost peak 0 within 200 generations. The population has almost entirely lost the ability to localize to either peak.

## Discussion

At high mutation rates, individuals with greater mutational robustness can outcompete those with higher fitness. Previous studies have not found a relationship between population size and the critical mutation rate, at which there is

a phase transition from survival-of-the-fittest to survival-of-the-flattest (Comas et al., 2005). However, the results of the current study suggest that population size does have an effect on the size of mutation rate that can be tolerated before the population loses the fittest and the flattest peaks, and that this is particularly noticeable in populations with 100 individuals or less. As shown in figure 2, the size of mutation rate at which each peak is lost for increasing population sizes can be approximated by an exponential function. One possible reason for this is that small populations are more susceptible to stochastic variation due to random genetic drift (Comas et al., 2005; Hartl and Clark, 2007); small populations with relatively large genomes cannot explore the entire neutral space of the landscape. Consequently, quasispecies formation is difficult, and the fitness peaks may be more easily lost. The dramatic reduction in critical mutation rate observed for small populations has implications for local extinction events in which there is a significant drop in population size. Further work will be necessary to apply this result to populations under threat of local extinction.

The dynamics of finite populations have very different properties compared to those of infinite populations, for example non-zero probability of extinction. The latter can be a good approximation of the former if the size of populations is large. However, where a small population size is fundamental to the issue of concern, as with the relationship established empirically in this paper, and in any work on extinction events (zero population size), such approximations break down. This situation is similar to statistical mechanics, where systems of large numbers of particles

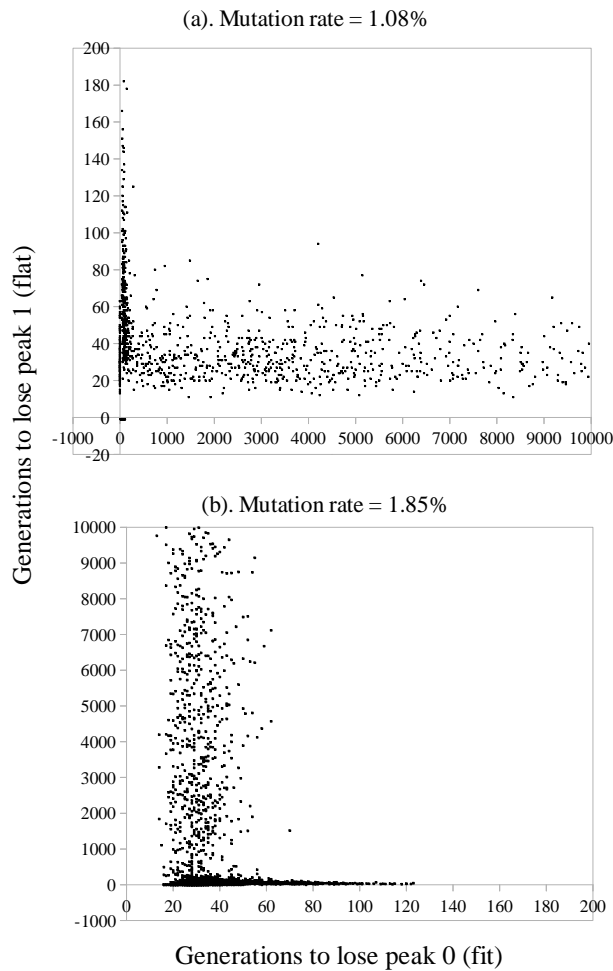

Figure 3: Transition from survival-of-the-fittest to survival-of-the-flattest and subsequently to the error catastrophe. Each point represents the number of generations it took to lose the high, narrow peak (peak 0) and the number to lose the lower, flatter peak (peak 1), in a single run of the GA for population size 100. Where a peak was not lost within 10,000 generations, a value of -1 was assigned for that particular run of the GA: all points on the negative side of either axis should be taken to have a higher value than 10,000. (a) The mutation rate by which 95% of the runs had lost peak 0 within the duration of the simulation; just 52% of these runs lost peak 1. This demonstrates that the transition from survival-of-the-fittest to survival-of-the-flattest is essentially complete. This can be considered as a critical mutation rate. (b) The mutation rate by which 95% of the runs had lost peak 1 within the duration of the simulation; 100% of these runs lost peak 0. This demonstrates that the transition from survival-of-the-flattest to the error catastrophe is essentially complete, with the population having almost entirely lost the ability to localize to either peak.

are approximated by laws derived for an infinite number of particles. The relation between the two is asymptotic and rooted in the law of large numbers. In fact, one can obtain equations for infinite populations from stochastic equations for finite populations by taking their expected value with respect to a probability measure on the population sizes  $m \in \{0, 1, \dots\}$ . The dynamics of finite populations can be described by stochastic differential equations. In particular, branching processes have been used to study the population dynamics of populations with variable (random) finite size (Jagers, 1975). The dynamics of finite populations have also been studied using the Moran process (Moran, 1962; Nowak, 2006). This work establishes an important empirical relationship between population size and critical mutation rate; the development of a corresponding theoretical model deserves further investigation.

Previous studies have defined the critical mutation rate to be the midpoint between the highest mutation rate at which there is survival-of-the-fittest, and the lowest mutation rate at which there is survival-of-the-flattest (Wilke et al., 2001; Comas et al., 2005). However, the results of this study clearly show that there is a transition from survival-of-the-fittest to survival-of-the-flattest and subsequently to the error catastrophe (figure 3).

## Conclusion

This study investigated whether or not there is a relationship between population size and the size of mutation rate that can be tolerated before fitter individuals are outcompeted by those that have a greater mutational robustness (the critical mutation rate). The results show that the sizes of mutation rate at which the high, narrow peak and the lower, flatter peak are lost for increasing population sizes can be approximated by an exponential function. The effect of population size on the size of mutation rate that can be tolerated before the population loses the fittest and the flattest peaks is particularly noticeable in small populations with 100 individuals or less. This provides new insight into the factors that can affect survival-of-the-flattest in small populations, and has implications for populations under threat of local extinction. Other factors, such as sequence length and distance between peaks, may well have a significant influence on both critical mutation rate and population sizes that can withstand specific rates of mutation. It will be beneficial to investigate this in the future, as well as to construct a theoretical model (whether based on differential equations or not) that can replicate the exponential relationship between critical mutation rate and population size, found here by experiment, for low population sizes.

In addition, there is clear evidence for a continuum of mutation rates representing a transition from survival-of-the-fittest to survival-of-the-flattest. This identifies a critical mutation rate by which the population has a 95% likelihood of losing the higher peak.

## Abstract

Biological populations often exhibit complex and efficient behaviors, where temporal and spatial couplings at the macro-scale population level emerge from interactions at the micro-scale individual level, without any centralized control. This paper specifically investigates the emergence of behavioral synchronization and the division of labor in a foraging swarm of robotic agents. A deterministic model is proposed and used by each agent to decide whether it goes foraging, based on local cues about its fellow ants' behavior. This individual model, based on the competition of two spiking neurons, results in a self-organized division of labor at the population level. Depending on the strength and occurrences of interactions among individuals, the population behavior displays either an asynchronous, or a synchronous aperiodic, or a synchronous periodic division of labor. Further, the benefits of synchronized individual behaviors in terms of overall foraging efficiency are highlighted in a 2D spatial simulation.

## Introduction

Nature displays fascinating examples of biological populations that achieve complex tasks without requiring any centralized control. How to efficiently achieve a distributed and decentralized control, a key issue for biological and artificial systems alike, is still far from being entirely elucidated (Camazine et al., 2001), although the interplay between the individual, micro-scale level and the population, macro-scale level has been extensively studied in the literature (see Beshers and Fewell (2001) for a survey).

This paper focuses on behavioral synchronization and the division of labor in a robotic swarm. On the biological and ethological side, behavioral synchronization and division of labor have been shown to enhance the adaptive value in various insect species such as spiders (Krafft and Pasquet, 1991), collembola (Leinaas, 1983), fireflies (Branham and Greenfield, 1996) and have also been observed in ants (Goss and Deneubourg, 1988; Cole, 1991). Experimental studies devoted to the foraging behavior in ant colonies suggest that synchrony might contribute to a better communication among agents (Bonabeau et al., 1998b), and significantly improves the foraging performance compared to asynchronous behaviors (Bonabeau et al., 1998a; Delgado

and Sol  , 2000). The emergence of synchrony is explained from both individual factors, e.g. internal individual mechanisms, and local interactions among individuals.

On the artificial and robotic side, the self-organized division of labor in an ant colony is nothing like easily mastered by a robotic swarm. Notably, in many cases the micro-scale models proposed in the ethology literature might exceed the plausible physical or cognitive resources of most simple agents (e.g. due to the required resources or the presence of random generators supporting stochastic models). The swarm robotics framework involves specific limitations; while it considers a large population<sup>1</sup>, power consumption remains a critical issue, entailing limited communication and computational abilities. Quite a few authors have been considering foraging robotic swarms in the last two decades (see Bayindir and Sahin (2007) for a survey), proposing hand-crafted architectures (be they bio-inspired (Labella et al., 2006; Panait and Luke, 2004) or not (Liu et al., 2007; Hauert et al., 2008)), or using evolutionary computation to optimize the individual decision model (Dorigo et al., 2005).

In the meanwhile, how to enforce the synchrony of individual behaviors has seldom be considered. Wischmann et al. (2006) and Hartbauer and Romer (2007) have investigated the use of coupled oscillator-based models, respectively considering an energy-foraging and a cleaning task. Taking inspiration from insect synchronous behavior such as chorusing male insects, both approaches illustrate how group synchronization can emerge from local communications. Trianni and Nolfi (2009) present a thorough study of swarm synchronization from the perspective of dynamic systems, notably using Evolutionary Computation to optimize efficient synchronization strategies.

Resuming an earlier work Chevallier et al. (2010), this paper presents a frugal model aimed at robotic swarm foraging, called *SpikeAnts*. This model, based on the coupling of two spiking neurons with different internal dynamics (Gerstner and Kistler, 2002), enables an individual

<sup>1</sup>Contrasting with early work on multi-robot systems; see (Parker, 2008) and references therein.

agent to decide whether it must go foraging based on local cues from other agents. Spiking neurons, now a well-established formalism, are known to display rich temporal dynamics and synchronization patterns (Paugam-Moisy and Bohte, 2011). From the individual decisions and interactions within *SpikeAnts*, synchronous and asynchronous population behaviors are shown to emerge depending on the range of interactions among the individuals. This paper investigates the implications and merits of synchronous behaviors in terms of overall foraging efficiency, where spatial interactions are modelled through a collision avoidance mechanism. Synchronous population behavior, decreasing the chances of collisions, result in more fluid individual trajectories and better foraging returns.

This paper is organized as follows. First, the notion of “foraging swarm” is specified. For the sake of self-containedness, the next section sums up the *SpikeAnts* model, explaining the spiking neurons used and their coupling. Afterwards, the notions of temporal and spatial couplings of agents’ behaviours in a swarm are discussed. Some conjectures on the benefits of synchrony are presented. The experimental setting proposed to study these conjectures is presented. The last section reports on the experimental results, discussing the trajectories of the robotic swarm in a simulated 2D environment. The paper concludes with a discussion and some perspectives for further research.

## Foraging swarm

Basically, the foraging task aims at securing a sufficient amount of food for the (ant) colony at any time. The foraging activity however is itself energy consuming. Therefore it would be inappropriate that all individuals in the colony devote themselves to foraging. Hence the dilemma is: On the one hand, sufficiently many individuals should devote themselves to foraging, but no more; On the other hand, the division of labor between the foraging individuals and the others has to be enforced without any centralized control. Although the division of labor might be resolved by task assignment at the individual level (deciding once for all whether a given individual is a foraging one), such a fixed mechanism would hardly account for the famed flexibility of ant colonies, where the division of labor smoothly adapts to emergencies.

The approach proposed by Liu et al. (2007) involves a probabilistic finite state automaton, where each individual obeys a Markov decision process involving a few states (e.g., resting, foraging, grooming). The probabilities of transitions among states are optimized using evolutionary computation in order to maximize the overall performance of the swarm. The efficiency of this approach thus relies on the size of the swarm, enforcing that the number of individuals in a given state at any point is close to the desired one due to the law of large numbers. Notably, it also requires any individual agent to embed a random generator. Displaying a “truly ran-

dom” decision making process is by no way a basic ability (human beings, for instance, are known to be poor random generators).

## The SpikeAnts model

The proposed individual model is inspired from both Goss and Deneubourg (1988) and Huang and Robinson (1999), where the agent decision results from internal and external factors, and the external factors reflect the other agents’ behavior (social inhibitions).

### Foraging and Social Inhibitions in *SpikeAnts*

Formally, the *SpikeAnts* model involves three states, respectively called *foraging* (active), *sleeping* (inactive) and *observing* (activable), with deterministic transitions (Fig. 1). When in sleeping state, the agent switches to the observing state after some time  $t_s$ ; when in foraging state, the agent switches to the sleeping state after some time  $t_f$ . The agent decision takes place in observing state, taking some cues from the agent’ relatives: essentially, if it sees many other foraging agents (in a sense made precise below) the foraging incentive is low and the agent switches to the sleeping state<sup>2</sup>; otherwise, it switches to the foraging state. This mechanism thus implements social inhibitions, as opposed to e.g. threshold models where the agent decision is based on internal thresholds only (Bonabeau et al., 1998a).

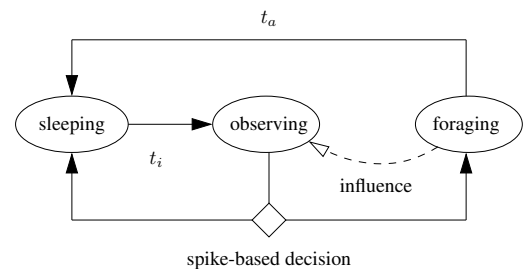

Figure 1: An agent is described by three states and the state transitions are indicated with black arrows. An observing agent decides to forage or not based on local information sent by neighboring active agents (white arrow).

### The competition of two spiking neurons

The agent decision in observing state is made through the competition of two spiking neurons. A model of spiking neuron describes the evolution of an internal variable, the membrane potential; the neuron fires an electrical pulse, called spike, when this membrane potential reaches a given threshold. By connecting spiking neurons to each other and

<sup>2</sup>Note that agents in sleeping state are not necessarily resting but might achieve other tasks as well; the extension of the current model to multi-task settings is a research perspective (see Discussion and Conclusions).

Figure 2: Membrane potentials of active (in dark/red) and passive (in gray/blue) neurons. The dashed line indicates the threshold  $\vartheta$ . Initially sleeping, the agent goes observing at time 20ms. As the active neuron fires before the passive one, the agent goes foraging and the active neuron sends spikes during the whole foraging period, signalling its activity to other agents. It then switches to sleeping state (from circa 50 to 70ms). A second observing period starts thereafter; this time the passive neuron fires before the active one. The agent then switches to sleeping state. At circa 90ms, a third observing period starts, and the agent switches to foraging almost immediately.

having them exchange information through spikes, a rich variety of dynamic activation and synchronization patterns can be obtained.

Formally, an agent is modelled as two spiking neurons, an active one and a passive one. The agent decision (foraging or sleeping) depends on whether the active or the passive neuron fires first. Both neurons are respectively inhibited and activated by the spikes coming from other agents, emitted when these are foraging.

The passive neuron is implemented as a Leaky Integrate-and-Fire (LIF) neuron (Gerstner and Kistler, 2002); the active one is implemented as a Quadratic Integrate-and-Fire (QIF) neuron (Hansel and Mato, 2001); both models have been extensively studied in the literature.

The passive LIF neuron is modelled by a differential equation, which describes the temporal evolution of a potential  $V_p$ . If  $V_p$  exceeds a threshold  $\vartheta$ , the neuron fires a spike and is reset to the resting potential  $V_{\text{reset}}^p$ .

$$\begin{cases} \frac{dV_p}{dt} = -\lambda(V_p(t) - V_{\text{rest}}) + I_{\text{exc}}(t), & \text{if } V_p < \vartheta \\ \text{else fires a spike and } V_p \text{ is set to } V_{\text{reset}}^p \end{cases} \quad (1)$$

where  $\lambda$  is the relaxation constant.  $I_{\text{exc}}(t)$  models instantaneous synaptic interactions. The set of presynaptic neurons is denoted by **Pre**, such that there exists a communication channel from every neuron in **Pre** toward the current neuron. Denoting **Train<sub>i</sub>** the spike train of the  $i^{\text{th}}$  neuron in **Pre**,

$$I_{\text{exc}}(t) = w \sum_{i \in \text{Pre}} \sum_{j \in \text{Train}_i} \delta(t - t_j^i), \quad (2)$$

where  $w$  is a synaptic weight,  $\delta(\cdot)$  is the Dirac distribution and  $t_j^i$  is the firing time of the  $j^{\text{th}}$  spike from the  $i^{\text{th}}$  presynaptic neuron.

The active QIF neuron is described by the evolution of the potential  $V_a$ , compared to the resting potential  $V_{\text{rest}}$  and an internal threshold  $V_{\text{thres}}$ . Additionally, it receives an internal signal  $I_{\text{clock}}$  modelling a gap junction connection:

$$\begin{cases} \frac{dV_a}{dt} = \lambda(V_a(t) - V_{\text{rest}})(V_a(t) - V_{\text{thres}}) \\ \quad + I_{\text{inh}}(t) + I_{\text{clock}}(t), & \text{if } V_a < \vartheta \\ \text{else fires a spike and } V_a \text{ is set to } V_{\text{reset}}^a \end{cases} \quad (3)$$

The choice of this neuron model (Izhikevich, 2007) is motivated by the bistability of the QIF neuron if the reset threshold is greater than the internal threshold ( $V_{\text{reset}}^a \geq V_{\text{thres}}$ ). If  $V_{\text{reset}}^a < V_{\text{thres}}$ , the membrane potential  $V_a$  stabilizes on  $V_{\text{rest}}$  when there is no external perturbation, and the neuron thus exhibits an integrator behavior. When  $V_{\text{reset}}^a \geq V_{\text{thres}}$ , the neuron displays a bursting behavior and fires periodically.

### An Agent Slice of Life

In observing state, the agent decision is thus controlled from the passive LIF neuron (Eq. (1)), the active QIF neuron (Eq. (3)) and an internal clock unit. Both spiking neurons receive the spikes emitted by other neighbor foraging agents (external factors); additionally, the active neuron receives the  $I_{\text{clock}}$  signal emitted by the agent internal clock. The active neuron is activated by the internal signal, and inhibited by the external signals, whereas the passive neuron is only activated by the external signals. Depending on whether the active (respectively the passive) neuron fires first, the agent goes foraging (resp. sleeping).

When the observing agent sees none or few other foraging agents (i.e. receives no or few spike signals from them), the internal signal  $I_{\text{clock}}(t)$  is not counteracted by any external inhibitions and the active neuron fires; it wins the competition and the agent goes foraging (first and third periods in Fig. 2). When in foraging state, the active neuron is bursting and periodically sends spikes to neighbor agents (which process them only if they are in observing state). The agent stays foraging for a time  $t_f$  and then switches to the sleeping state for a time  $t_s$ . This switch is triggered by an internal delay between the clock unit and the active neuron.

If the observing agent perceives many foraging agents, the passive neuron receives many excitatory external signals and it fires first (second period in Fig. 2); the agent switches to sleeping state for a time  $t_s$ .

Overall, the competition between the passive and active neurons thus fully determines the observing agent decision. It is worth noting that the SpikeAnts system is asynchronous<sup>3</sup>. Its temporal dynamics is highly non-linear; in

<sup>3</sup>Differential equations are solved by finite differences, with fixed precision depending on the computational resources.

Figure 3: *SpikeAnts* simulation in 2D environment. (a) The arena includes a nest and a food regions (disk); foraging, sleeping and observing agents are respectively indicated with squares, circles and triangles. (b) Proximity zone of an agent. (c) Communication range  $\rho$ .

practice, the number and pace of the spikes received before making a decision vary from one observing period to another. There is no time limit for the observing state; an agent remains in observing state until making a decision.

### Investigating Temporal and Spatial Couplings

In a first study (Chevallier et al., 2010), the temporal couplings induced by *SpikeAnts* have been experimentally studied within an abstract setting, considering each agent as a node in a random graph with a given connectivity rate. Each agent had a fixed position and a fixed, sparse, set of neighbors. In particular, no traveling time from the nest to the food source was accounted for in the foraging activity. Such an abstract setting however does not account for the fact that real and artificial agents alike are moving in a spatial environment, and can hardly be considered as material points.

A more realistic simulated environment is investigated in the present paper. This section introduces the experimental setting and goals.

### Spatial interactions

The study considers a large square 2D arena, the dimension of which is circa 160 times the size of the individual agent. The arena includes the nest, or sleeping place, and the food source, or foraging place (Fig. 3(a)). The region centered on the nest (respectively the source) with radius  $\gamma$  is referred to as nest (resp. source) region. The region centered on the nest with radius  $2\gamma$  is referred to as domestic region ( $\gamma=3\%$  of the arena size in the experiments).

Each agent moves with a constant speed; its communication range  $\rho$  is constant (Fig. 3(c)). The agent is endowed with a set of elementary behaviors:

- In observing state, the agent moves inside the domestic region, with constant speed, except when it sees another agent, where the collision avoidance behavior is executed (see below). Foraging agents within its communication

range send excitatory (resp. inhibitory) signals to its passive (resp. active) neuron.

- Upon the firing of its active neuron, the agent switches to the foraging state for a given time  $t_f$ . Whatever its current position, it goes directly to the food source with constant speed, except when it sees another agent, where the collision avoidance behavior is executed. When arriving in the source region, the agent moves inside this region until the foraging time  $t_f$  is elapsed.
- When switching from foraging to sleeping state, the agent goes directly to the nest region with constant speed, except when the collision avoidance behavior is executed. When arriving in the nest region, the agent moves inside the domestic region until the sleeping time  $t_s$  (starting at the end of the foraging period) is elapsed.
- When switching from observing to sleeping state, the agent stays in the nest region, moving with constant speed, except when the collision avoidance behavior is executed.
- The collision avoidance routine is triggered whenever an obstacle or another agent is located in the proximity zone of the current agent (Fig. 3(b)). The obstacle side is detected as the side (left or right) with higher average sensor activation, and the agent rotates in the opposite direction with a given angle  $\alpha$  ( $\alpha = 5^\circ$  in the experiments). It goes straight ahead in the subsequent time steps (unless some further obstacle enters in its proximity zone, in which case the collision avoidance is triggered anew). When its proximity zone becomes empty again, the agent rotates back to its initial direction.

### Goal of experiments

The experiments are meant to answer two main questions. The first one concerns the temporal couplings between the swarm agents. In the former graph-based setting, several

behavioral regimes were observed depending on the connectivity of the neighborhood graph (agent sociability), ranging from asynchronous behaviors to synchronous aperiodic and synchronous periodic. A 2D environment however involves several sources of variability, which might prevent the swarm from reaching a synchronous behavior. Firstly, the transitions from observing to foraging states are no longer instantaneous as agents must travel from the nest to the source. Secondly, the set of neighbors of each agent varies as the agent moves in observing state, whereas the connectivity was fixed in the previous experiments. Lastly, the agent activity might be perturbed as the collision avoidance routine is executed in priority whenever the agent meets an obstacle or another agent. The question thus is whether the regimes observed in the fixed graph-based setting are still observed in 2D simulations, and whether the transitions from one regime to another depend on the same design parameters.

The second question concerns spatial couplings, and the possible impact of synchronous behavior on the collective foraging efficiency. Whereas synchronous activity is ubiquitous in many living societies and complex systems, the benefits of synchrony remain actively debated. On the one hand, when agents move in a synchronous way as a flock, the chances of collision expectedly decrease and more agents might make it to the source. On the other hand, in asynchronous mode some agents might be deviated from their route to the source due to repeated collision avoidance (“traffic jams”); but it might also be the case that asynchronous agents better share the collective space and the frequency of traffic jams decreases. In order to investigate further the foraging efficiency, two indicators are proposed. The first one counts the *number* of agents arriving at the food source; the second one measures the overall foraging *time*, i.e. the overall number of time units spent by agents in the source region.

## Experimental setting

The experimental setting used to answer the above questions goes as follows. Each agent is simulated as a Khepera robot with eight infra-red sensors and a radio communication module. The communication range  $\rho$  is constant, covering 20% of the arena unless indicated otherwise. Each foraging agent broadcasts its activity signals to all agents with distance less than  $\rho$ ; each observing agent receives the signals of foraging agents on an individual basis. In other words, the simulated setting involves no centralized communication among agents.

At the beginning of each simulation, every agent is sleeping and wakes up after some time, independently and uniformly drawn in  $]0, 2t_s[$ . Each simulation involves 50,000 time steps. All reported results are averaged over 10 independent runs for a given parameter setting. As already mentioned, the *SpikeAnts* model is deterministic; the only source

of variation among simulations comes from the swarm initialization and the uniform agent wake-up times.

Every agent obeys the same *SpikeAnts* model with same parameters as in Chevallier et al. (2010). Foraging and sleeping times are chosen such that their ratio is not an integer, to avoid spurious synchronization effects:  $t_f = 541$  and  $t_s = 457$  time steps. Spiking neurons are simulated using a clock-driven simulator and Runge-Kutta method for differential equation approximations with a small time step of 0.1ms to achieve numerical stability.

## Experimental Results

This section reports on the temporal and spatial couplings observed in the 2D simulation of *SpikeAnts*.

### Emergence of Temporal Self-Organization

The temporal coupling at the population level is displayed in Fig. 4, reporting the number of active agents vs the simulated time step. Three behavioral regimes emerge depending on the parameter setting. An *asynchronous* regime (Fig. 4, (A)) is observed for low communication ranges; agents individually and asynchronously decide to go foraging, with an average number of 30 foraging agents in each time step out of 100 agents. Another *synchronous aperiodic* regime sees the emergence of sub-populations of agents, that synchronously decide to go foraging; still the size of the foraging subpopulation varies from one period to another one, and the foraging subpopulations with same size gather distinct agents in each period (Fig. 4, (B)). Finally, the *synchronous periodic* regime involves a few persistent subpopulations (two in Fig. 4, (C)), which alternate and go foraging. The agent trajectories in all three regimes are shown in Fig. 5, displaying different spatial patterns.

The emergence of these regimes has been explained from a few *SpikeAnts* design parameters (Chevallier et al., 2010). The first factor is the communication range  $\rho$ , given as percentage of the arena covered when agents broadcast/receive the foraging signal. For a low  $\rho$ , the agent decision is based on a few local cues; for a high  $\rho$ , every agent can reliably estimate the number of currently foraging agents. The second factor is called *receptivity* and characterizes the strength of interactions between agents; it is expressed as the ratio between the connection weight  $w$  and the sub-threshold range (depending of the resting potential  $V_{rest}$  and the firing threshold  $\vartheta$ ):  $\left| \frac{w}{\vartheta - V_{rest}} \right|$ . With a high interaction strengths, a few spikes can trigger the agent decision; small variations in the received information lead to different decisions. With a low interaction strength, agent decisions are based on many signals; the number of spikes needed to reach the threshold is high and the agent decision thus is more stable.

The transition between all three regimes is made precise using an entropy indicator defined as follows. Let  $n_t$  denote the number of foraging agents at (simulated) time  $t$ ,

Figure 4: Three behavioral regimes emerge in the population: (A) Asynchronous, (B) Synchronous aperiodic and (C) Synchronous periodic. Each graph reports the number of active agents *vs* the simulated time step.

Figure 5: Trajectories followed by agents during a representative run, respectively in asynchronous (A), synchronous aperiodic (B) and synchronous periodic (C) regimes. Darker lines indicated the most often visited paths.

with  $0 \leq n_t \leq M$  and  $M = 100$  is the overall number of agents. Let  $p_n$  denote the percentage of time steps such that  $n_t = n$ . The foraging entropy is classically defined as  $H = -\sum_{n=0}^M p_n \log p_n$ . The phase diagram, reporting the entropy *vs* the two control parameters of agent sociability and receptivity, is displayed in Fig. 6.

The asynchronous regime is characterized by a medium entropy value (circa 3) as the  $n_t$  values are tightly distributed around a mean value. This regime emerges in populations with low communication range and high interaction strength. For a medium communication range and weak interactions, a synchronous aperiodic activity is observed, with high entropy ( $H \approx 4$ ) as the sub-population sizes vary from 10 to 80 agents. A stable synchronous periodic regime, characterized by a low entropy value ( $H \approx 1$  since the sub-population sizes are very stable), is observed for a large communication range and strong interactions. On Fig. 6, the synchronous periodic regime emerges for a communication radius which cover nearly all the arena ( $\rho = 80\%$ ). Complementary experiments show that for a smaller  $t_f/t_s$  ratio the transition from asynchronous to synchronous regimes is shifted on the left, and occur for smaller communication range ( $\rho = 30\%$ , results omitted for brevity).

Figure 6: Phase diagram of the temporal coupling: foraging entropy *vs* the agent sociability (*x* axis) and receptivity (*y* axis).

Figure 7: Foraging efficiency defined as the percentage of foraging agents that arrive in the source region.

### Mixed Benefits of Synchronous Foraging

As mentioned earlier on, it was expected that synchronous regimes would benefit the foraging activity through decreasing the chance of collisions. The foraging efficiency measuring the fraction of foraging agents making it to the source is displayed in Fig. 7; on average, 80% of the foraging agents arrive in the source region in synchronous periodic regime, as opposed to less than 40% in asynchronous regime. The lower foraging efficiency in asynchronous regime is related to the “price of anarchy”: more chances of collisions slow down the agents on their way to the source region, to the point that the foraging period ends up for most agents before they even reach the source, and they go back to the nest with empty hands.

Additional experiments are conducted to examine the sensitivity of the synchrony benefits when increasing the foraging time  $t_f$ . For larger  $t_f$  values, all agents eventually arrive at the source sooner or later. It thus comes naturally to consider the agent traveling time  $t_r$ . By construction,  $t_{min} \leq t_r \leq t_{max} = t_f$ , where  $t_{min}$  is the minimum time needed to go from the nest to the source. Let us accordingly define the *foraging loss* as the excess time wasted in the travel from the nest to the source,  $L = \frac{t_r - t_{min}}{t_{max} - t_{min}}$ . A contrasted picture then appears (Fig. 8): the foraging loss is minimum in asynchronous regime (less than 50%), and it increases when the swarm switches to synchronous aperiodic or periodic regimes (up to 65%). Agent paths shown on Fig. 5 corroborate these results: agents in synchronous regimes display more spatially distributed trajectories than in asynchronous regime, thus increasing the traveling time.

This experiment suggests that synchronous foraging entails opposite effects: while less agents arrive at the food source in asynchronous regime, the overall foraging time remains higher than for synchronous regimes. Additional experiments will examine these mixed effects in more depth.

### Discussion and Perspectives

This paper has presented the distributed, decentralized and deterministic swarm model *SpikeAnts*, accounting for the emergence of synchronous behaviors and division of labor in

Figure 8: Foraging loss  $L = \frac{t_r - t_{min}}{t_{max} - t_{min}}$ , measuring the foraging time wasted in the travel from the nest to the source.

a foraging swarm. Depending on the communication range and interaction strength among agents, the swarm behavior ranges from an asynchronous regime, where every agent independently makes its decisions, to a synchronous periodic regime where two persistent sub-populations alternate and go foraging.

A most interesting and unexpected experimental result concerns the mixed effects of synchrony. Quite a few authors have advocated the benefits of synchrony for division of labor: temporal coactivation of individuals enhance the information exchange and the cohesion of the population (Robinson, 1992; Bonabeau et al., 1998b; Delgado and Solé, 2000); synchrony also provides an intrinsic mechanism of mutual exclusion (Hatcher et al., 1992). In a 2D framework however, agent synchronization entails some spatial couplings through the collision avoidance mechanism. The experimental evidence suggests that synchronous flocking behaviors decrease the chances of collision (and more agents arrive at the target destination), but increase the traveling time (and agents have less time to achieve the task when arrived at destination).

Additional experiments will be needed to investigate these effects, and a first perspective is to implement *SpikeAnts* on a physical robotic platform. As already mentioned, *SpikeAnts* was designed to comply with limited memory and computational resources. Along the same lines, *SpikeAnts* will be extended to deal with several tasks of diverse priorities (e.g., collecting energy and rescuing the swarm robots out of energy). The question is whether and when the swarm will demonstrate several sub-populations attending the different tasks in a synchronous way, and how the division of labor may take place depending on the experimental setting.

A further question regards how the collective regime will be modified under external perturbations in the environment, and how the swarm adapts its response. A yet further stage will be to consider autonomous and adaptive agents, e.g. controlling their foraging time or interaction strength depending on their internal state and individual agenda.

## Abstract

We hypothesise that degeneracy in the components of an artificial chemistry (AChem) facilitates the complexity of the system as a whole. We introduce definitions of degeneracy and redundancy, and show how these quantities can be calculated for the binding system of an AChem.

We present a case study using the AChem Stringmol, in order to support our hypothesis. We demonstrate that the binding system in Stringmol has degeneracy and we create a deliberately poor variant: ‘sticky-Stringmol’, that has a binding system with no degeneracy. Comparing sticky-Stringmol to Stringmol, we note the loss of many simulation artifacts that have been used as evidence of the complexity of Stringmol, including: emergent macro-mutations, hypercycles, sweeps and parasite evasion. These results are evidence that degeneracy in the components of an AChem facilitates the complexity of the system as a whole.

## Introduction

Degeneracy is the ability of elements that are different, in some respect, to perform the same role in some, but not all, situations. Degeneracy is a noticeable property of many biological systems, and is observable on many scales within those systems [7] and has been linked to the evolvability and robustness of these systems [16]. Examples range from molecular interactions and gene networks [7], the connectivity of neurons in the brain [13], through to social networks [15]. Complexity and degeneracy have been strongly linked [14]. Attempts have been made to describe these concepts into mathematically meaningful, and consequently unambiguous formulae [14][7].

Just as degeneracy can be observed on many scales in nature, so it should be in artificial chemistries (AChems) that aspire to achieve the levels of complexity that exist in the natural world. We hypothesise that degeneracy in the components of an AChem will facilitate complexity of the system as a whole. We introduce measures of degeneracy and redundancy in terms of an ‘interaction function’ between two sets. We use binding between two sets of chemicals in an AChem (defined below) as a concrete example of an interaction function. We demonstrate that the degeneracy in

the binding system of Stringmol [10] is particularly important for the complexity of the AChem as a whole.

When presenting the complexity of an AChem, it is standard practice to present simulation results and focus on an artifact that the system has been able to produce as evidence of the complexity of the AChem. Examples of artifacts include: the ability to ‘compute’ prime numbers [1]; the generation of cooperative organisations [9], hypercycles [10] and autocatalytic sets [12]. However, the complexity available in current AChems is still well below that of the natural world.

The presentation of simulation artifacts is currently the only available way to evaluate AChems (see [4]). As such, two chemistries that produce different types of artifact can only be compared in a qualitative manner. Progress has been made on formalising artifacts in chemistries, and automating the discovery of autocatalytic sets [12] and organisations [5]. However, simulation artifacts can only be measured *a posteriori*: they can not be determined at design stage. The degeneracy measure we introduce can be applied at the design stage to the components of an AChem, thus allowing sources of complexity to be designed in.

## Binding in AChems

In this paper, we focus on degeneracy in the context of binding in AChems. In the ‘ $(S, R, A)$ ’ definition of AChems [4],  $S$  is a set of chemicals,  $R$  is a set of reactions between the chemicals and  $A$  is the algorithm that applies reactions from  $R$  to chemicals from  $S$ . For example, if the chemicals in set  $S$  are integers, then the set  $R$  of reactions might contain all reactions of the form:

$$a + b \mapsto c \quad \text{if } c = \frac{a}{b} \text{ is an integer.} \quad (1)$$

This is the prime number generation chemistry [1].

The important point for this discussion is the binding rule: “if  $\frac{a}{b}$  is an integer”. This can be viewed as an “if-then” statement: if the binding rule is true, the reaction may proceed. The left hand side (LHS) of the reaction, “ $a + b$ ”, is the if part of this statement. The right hand side (RHS) of the reaction, “ $\mapsto c$ ”, is the then part. Looking at the chemistries reviewed in [4], the vast majority have a trivial LHS, where

the *if* simply tests if two molecules are presented by the algorithm, *A*. The only AChems we are aware of with a non-trivial LHS are Primes [1], AlChem [9], Stringmol [10], Molecular Classifier Systems [3] and RBN-world [8].

AlChem (level 0) had relatively simple binding, which resulted in the collapse of the system into ‘self-replicators’. In AlChem (level 1), binds that would result in reactions that propagate self replicators were restricted. As a result of the enriched binding rule, AlChem (level 1) produced more complex artifacts, including ‘cooperative organisations’ [9]. This example helps support our hypothesis that binding is an important component of an AChem, and that changes to this component can change the level of complexity observed in the system.

## Organisation of the Paper

We define degeneracy and redundancy in an unambiguous manner, and introduce methods to measure these quantities. We justify introducing a new measure of degeneracy instead of adopting previously published measures. We use our measures to analyse the binding system used in Stringmol and demonstrate that the binding system is capable of producing degeneracy. We also use these measures to demonstrate that ubiquitous binding is unable to produce degeneracy. We use ubiquitous binding to define a deliberately poor Stringmol variant: ‘sticky-Stringmol’. We replicate the experimental procedures of [10] in order to compare the artifacts of ‘sticky-Stringmol’ and Stringmol. We give an overview of the previously undetected phenomena of ‘parasite evasion’ in Stringmol containers. The two mechanisms by which the container is able to survive a potentially fatal parasite are linked to binding. We also find that sticky-Stringmol containers are unable to evade a parasite.

## Degeneracy and Redundancy

We formally introduce and define redundancy and degeneracy in abstract terms, and provide a worked example calculating the redundancy and degeneracy of the binding system of a fictitious AChem.

In order to make an unambiguous statement of redundancy or degeneracy, one must state three pieces of information: Two sets of elements, *A* and *B*, that are being compared, and the method of comparison, defined by an ‘interaction function’,  $f : A \times B \mapsto \{0, 1\}$ , stating whether an element of *A* and an element of *B* interact or not.

If we consider an arbitrary element,  $a_m$  of set *A*, we can define a subset  $B_{a_m} \subseteq B$ , in terms of  $(a_m, f, B)$ , containing all the elements of *B* that  $a_m$  interacts with:

$$B_{a_m} = \{b \in B \mid f(a_m, b) = 1\}. \quad (2)$$

Elements  $a_m$  and  $a_n$ , are *redundant* if

$$\mathcal{R}(a_m, a_n \mid f, B) \Leftrightarrow B_{a_m} = B_{a_n}. \quad (3)$$

Elements  $a_m$  and  $a_n$ , are *degenerate* if

$$\mathcal{D}(a_m, a_n \mid f, B) \Leftrightarrow (B_{a_m} \neq B_{a_n} \ \& \ B_{a_m} \cap B_{a_n} \neq \emptyset). \quad (4)$$

The definitions in equations 3 and 4 equip us to deal with questions concerning individual examples such as ‘are  $a_1$  and  $a_2$  degenerate or redundant in a given context’. The ability to determine if  $\mathcal{D}(a_1, a_2 \mid f, B)$  is true, does not equip us to answer more general questions, such as what is the degeneracy of a set in a given context,  $\mathcal{D}(A \mid f, B)$ .

Degeneracy and redundancy, even when clearly defined between elements, have a non-trivial interaction within a set. Consider: sets  $C, D = \{a, b, c, d, f, g\}$ , and some interaction function *f* that causes the resulting matrix, which can be viewed as a network, to contain examples of both degeneracy and redundancy, see figure 1a. Consider also  $A, B = \{a, b, c, d, e, f, g\}$ , where *e* is part of a redundant set with *a*, see figure 1b. True measures of degeneracy and redundancy should detect that the redundancy of the set *C* is different from the set *A*. However, is the degeneracy of set *C* the same as the degeneracy of set *A*? If one wishes to maintain degeneracy of a set and redundancy of the set as orthogonal concepts, then the answer to this question must be ‘no’. If one answers ‘yes’, then the concept of the degeneracy of a set becomes conflated with the redundancy of the set. As a result of this conflation, such measures of degeneracy lose their value, as the results they give may be skewed by redundancy. This is why we introduce a new measure of degeneracy, rather than adopting an existing measure. The key to understanding the relationship between degeneracy and redundancy, is knowing that it is possible to measure the redundancy of a set without regard for the degeneracy of a set, but not the other way around.

It is, however, possible to construct a measure of degeneracy of a set that does not suffer from this conflation with redundancy, keeping the mathematical concepts of degeneracy and redundancy of sets orthogonal. We introduce such a measure here. Our method avoids the conflation problem by accounting for the redundancy of the two sets (in the contexts of an interaction function *f*) and constructing new sets that have no redundancy. The set  $\hat{A}$  is constructed from the set *A* (in the context of set *B* and the interaction function *f*) such that the elements  $\hat{a} \in \hat{A}$  are the redundant sets of *A*. We can construct  $\hat{B}$  in a similar manner. Note that it makes no difference if we construct  $\hat{B}$  in the context of  $\hat{A}$  or the context of *A*. These constructions can take place in any order and all examples of degeneracy that exist in  $(A, B)$  are maintained in  $(\hat{A}, \hat{B})$ .

Each element  $\hat{a}$  of the reduced set  $\hat{A}$  is itself a set containing one or more redundant elements from *A*. It is on these redundant sets that we base our measure of degeneracy. If we reconsider the above thought experiment, it can be seen that the element *e* will join an existing redundant set, see figure 1 parts (c) and (d). Consequently it will not

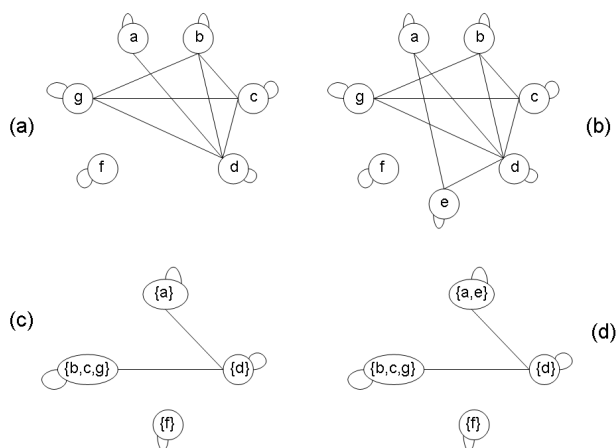

Figure 1: A network example of interaction between elements of a set. Two nodes  $x$  and  $y$  are joined with an edge if  $f(x, y) = 1$ . (a) is an example of an interaction containing examples of both degeneracy and redundancy by the definitions given in equations 3 and 4. In (b) the element ‘ $e$ ’ has been added. The elements  $a$  and  $e$  form a redundant set  $\{a, e\}$  as they both bind to elements  $\{a, e, d\}$ . (c) and (d), show the same relationships as (a) and (b) respectively, but in terms of redundant sets rather than elements.

affect a measure of degeneracy that is based on the elements of  $\hat{A}$  (the redundant sets of the elements of  $A$ ), instead of the elements of  $A$ .

We follow the definitions of redundancy and degeneracy for pairs of elements, and define redundancy and degeneracy for sets. Firstly, we consider an arbitrary element of set  $\hat{A}$ ,  $\hat{a}$ , and define the subset  $\hat{B}_{\hat{a}_m} \subseteq \hat{B}$ . This contains all the redundant sets of  $\hat{B}$  that  $\hat{a}$  interacts with:

$$\hat{B}_{\hat{a}_m} = \{\hat{b} \in \hat{B} \mid f(\hat{a}_m, \hat{b}) = 1\}. \quad (5)$$

We define the *redundancy of the set  $A$* , in the context of  $(f, B)$ , as the set of sizes of redundant sets of  $A$ :

$$\mathcal{R}(A \mid f, B) = \{|\hat{a}| \mid \hat{a} \in \hat{A}\}. \quad (6)$$

$\mathcal{R}(A \mid f, B)$  takes the form of a set of size  $|\hat{A}|$ ; the elements of this set are the sizes of the sets  $\hat{a} \in \hat{A}$ .

We define the *degeneracy of the set  $A$*  in the context of  $(f, B)$ :

$$\mathcal{D}(A \mid f, B) = \{|\hat{B}_{\hat{a}}| \mid \hat{a} \in \hat{A}\}. \quad (7)$$

$\mathcal{D}(A \mid f, B)$  also takes the form of a set of size  $|\hat{A}|$ ; the elements of this set are the numbers of redundant sets in  $\hat{B}$ , that each element  $\hat{a} \in \hat{A}$  interacts with.

### Worked Example

We define  $A, B = \{a, b, c, d, e, f, g\}$  to be all the chemicals in our fictitious chemistry. Note that for the purposes of this

example, we do not need to specify the reaction rule, as the products of reactions do not concern us in this calculation. We assume the binding rule returns a probability; we can apply a threshold at zero in order to construct an interaction function  $f$ . The result of the thresholding is shown in figure 2a. As it contains only binary values, it is an interaction matrix and the definitions of degeneracy and redundancy given in equations 3 and 4 apply (as in figure 1b).

We now construct the redundant sets: In figure 2a the row  $a$  and the row  $e$  have the same values, as such they are redundant under the definition given in equation 3. Similarly, rows  $b, c$  and  $g$  all have the same values. We can construct the redundant sets  $\hat{A} = \{\{a, e\}, \{b, c, g\}, \{d\}, \{f\}\}$ ; if we apply the same process to the columns, we obtain the reduced matrix shown in figure 2b (as in figure 1d).

The sizes of the redundant sets, shown in the row labels in figure 2b, make up the redundancy set,  $\mathcal{R}(A \mid f, B) = \{2, 3, 1, 1\}$ , shown in figure 2c. In order to quantitatively compare binding systems from different chemistries of different sizes we scale the redundancy set by dividing the values in the set by the average redundancy. The average redundancy is given by the sum of the set sizes divided by the number of sets; in this case  $(2+3+1+1)/4 = 7/4$ . The scaled redundancy set is the redundancy set divided by the average redundancy, shown in figure 2c.

From the reduced interaction matrix in figure 2b, it is also possible to calculate the degeneracy set. The degeneracy of set  $A$  is obtained by summing the respective rows in the reduced interaction matrix in figure 2b, the result,  $\mathcal{D}(A \mid f, B) = \{2, 2, 3, 1\}$ , is shown in figure 2d. The degeneracy of set  $B$  would be obtained by summing the columns. Note that the calculation of degeneracy is not based on the elements of set  $A$ , but is instead based on  $\hat{A}$ , the redundant sets of  $A$ .

We rescale the degeneracy set by dividing the degeneracy set by the average degeneracy. The average degeneracy is calculated by summing all the elements in the interaction matrix in figure 2b and dividing that by the number of rows,  $|\hat{A}|$ . In this case the average degeneracy is  $8/4=2$ . The scaled degeneracy set is shown in figure 2d.

These scaled sets can be used to compare the spread of redundancy and degeneracy when the systems being compared are of different sizes. A scatter plot is ideal for such a comparison, the rescaled degeneracy and redundancy sets from the worked example are shown in figure 3. If the systems being compared are the same size then it is appropriate to use the unscaled sets, allowing comparison of both the relative spread and the actual values of redundancy and degeneracy.

## Results

We apply our measures of degeneracy and redundancy (defined in equations 6 and 7) to the binding system used in Stringmol and to ‘ubiquitous binding’ (all molecules bind). This makes ubiquitous binding a good candidate for testing

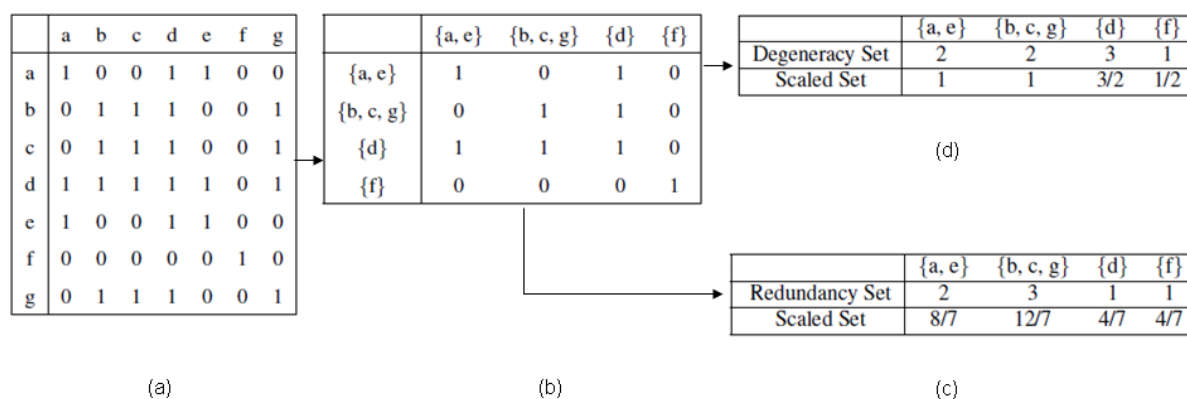

Figure 2: (a): The interaction matrix:  $\{a, b, c, d, e, f, g\}$  are the chemicals of set  $A$ , 1 indicating two molecules bind and 0 indicating two molecules do not bind. (b), the reduced matrix: The elements of  $\hat{A}$  are the redundant sets of  $A$ , these sets are given explicitly as the row and column labels. (c): The redundancy set and scaled redundancy set, for set  $A$ . The values of the redundancy set are the number of elements in row labels of (b). The scaled redundancy set is obtained by dividing the unscaled set by the average redundancy. (d): The degeneracy set and scaled degeneracy set for set  $A$ . The values of the degeneracy set are the number of ones on each row in the reduced matrix (b). The scaled degeneracy set is obtained by dividing through by the average degeneracy in  $\hat{A}$ .

Figure 3: Redundancy and degeneracy scatter plot for set  $A$  in the worked example. Each point in the scatter represents a redundant set (an element of  $\hat{A}$ ). The position on the redundancy axis is given by the scaled redundancy set shown in figure 2(c). Similarly, the position of the degeneracy axis is given by the scaled degeneracy set shown in figure 2(d). The redundancy and degeneracy sets are scaled such that the center of mass of the scatter plot is at (1, 1).

our hypothesis: that a more simplistic approach to binding will negatively impact the complexity of the artifacts observed in simulations. We apply the methodology of [10] to sticky-Stringmol and compare our results. We then describe how mid run parasites are evaded in Stringmol and how the mechanism for evasion is lost in sticky-Stringmol.

In our general comparison with Stringmol, as well as in the parasite trial, sticky-Stringmol is effectively the control experiment. By having a deliberately poor variant of String-

mol, we are able to establish which simulation artifacts are dependent on the degeneracy of the binding rule.

### Measuring degeneracy

The Stringmol alphabet is 33 characters: 7 ‘functional’ characters  $\{\$, \>, \wedge, \text{?}, =, \%, \}$ , and 26 ‘non-functional’ characters  $\{A - Z\}$ . Functional characters in Stringmol can contribute towards a bind site, but they contribute half as much as non-functional characters (for the full details, see [11]). We present results for the reduced character set:  $\{AB\%CD\}$ , containing 1 functional character and 4 non-functional characters, as the calculation for the full character set is intractable. We use the tailored Smith-Waterman algorithm [11] to calculate the bind strength of all strings of length 6 from this alphabet, and threshold at a Smith-Waterman score of 0.75 to produce an interaction function.

Degeneracy and redundancy for the set of all strings of length 6 are shown in figure 4. We also present the degeneracy and redundancy for the ubiquitous binding system used in sticky-Stringmol (under the same conditions) on the same figure, to allow a direct comparison of the properties of the two binding systems. We argue only that the tailored Smith-Waterman algorithm is capable of producing degeneracy and redundancy, not the specific levels of this which can be achieved for a string of arbitrary length. For ubiquitous binding, the matrix of interactions is filled with ‘1’ in every element, the result that it is maximally redundant scales to strings of any length and character set.

Ubiquitous binding has trivial redundancy and no degeneracy, which makes the comparison in figure 4 appear unnecessary. However, this is a simple example of a general technique that, for a given alphabet, can be used to compare

Figure 4: Comparison of the properties of the binding systems of Stringmol and sticky-Stringmol. The comparison shows the unscaled redundancy and degeneracy sets as the two systems contain the same number of elements. Each of the circles is associated with a redundant set. All of the circles together represent the Stringmol binding system. Sticky-Stringmol has only one triangle, as all of its elements form a single redundant set. It can be seen that the Stringmol binding system has a spread of both degeneracy and redundancy, whereas sticky-Stringmol’s ubiquitous binding has only trivial redundancy.

two or more binding systems of any level of degeneracy and redundancy.

### Degeneracy Affecting Simulation Artifacts

Stringmol is an AChem that encodes ‘microprograms’ as strings of characters. We give a brief overview of Stringmol here (for more details, see [11]). Each molecule is a string of characters that encodes a sequence of instructions, making use of pointer manipulations. A number of molecules are initialised in a reaction container. Pairs of molecules in the container are given an opportunity to react by the physics engine. In a biological system, although there may be thousands of different species of molecules, we note that in the majority of possible pairwise combinations, the number of molecules that each molecule interacts with is relatively small. As a result, care was taken in the design of Stringmol to check if two molecules could bind or not via a rich binding system. We made use of a tailored variant of the Smith-Waterman string-matching algorithm [11]. The Smith-Waterman algorithm is used in the study of Biology to compare the similarity of two sequences of DNA. In Stringmol, the Smith-Waterman based binding algorithm determines:

- with what probability two molecules bind;
- given that they bind, how the molecules are aligned;
- which molecule is the executing microprogram, and where its pointers are initialised.

Simulation Artifacts in Stringmol	Binding system property	
	Degeneracy	No Degeneracy
Self replication	✓	✓
Parasites	✓	✓
Random walks	✓	✓
Sweeps	✓	×
Macro-mutations	✓	×
Hypercycles	✓	×
Parasite evasion*	✓	×

Table 1: Comparison of system level properties, used to evaluate the level of the complexity of an AChem. Degeneracy denotes the original Stringmol binding system, No Degeneracy denotes the ubiquitous binding system used in the sticky-Stringmol variant. \* ‘Parasite evasion’ was not originally on the list of Stringmol’s properties published in [10]; we introduce it and present evidence that it occurs in Stringmol, but not in sticky-Stringmol.

In 1000 trials of Stringmol, numerous phenomena were observed, including the emergence of hypercycles (two mutually dependent molecules), macro-mutations (non-point based mutations), sweeps (change of dominant replicase, other than by a random walk) and parasites [10].

The hypothesis is that: by changing the level of degeneracy in the binding system of an AChem, we will alter the simulation artifacts. We investigate this proposed link by comparing Stringmol and sticky-Stringmol (with the full character set). The degeneracy and redundancy of these two binding systems (for a particular character set) is shown in figure 4. We repeated the experimental protocol of [10], running 500 trials of sticky-Stringmol to observe the diversity that arises from a mono-culture. Table 1 shows a comparison of the observed simulation artefacts. Sticky-Stringmol makes use of ubiquitous binding (no degeneracy), as opposed to the Smith-Waterman based binding of Stringmol (degeneracy).

The instruction set used in sticky-Stringmol is the same as the instruction used set in Stringmol. This might lead one to expect they should have computational artifacts of equal complexity; we find this is not the case, see table 1. These results show that a naive binding system, such as ubiquitous binding, can suppress complexity in an AChem. This identifies binding systems to potentially be an important aspect in all AChems.

These results indicate that the binding system has a strong effect of the overall complexity of the system.

### Parasite Evasion in Stringmol Containers

Having presented the main results of the paper, we now present evidence of parasite evasion in Stringmol. For our purposes: a ‘parasite’ is a molecule that is replicated, but is unable to replicate other molecules in return. ‘Parasite evasion’ is when *the container survives* the introduction of a

```

```

Figure 5: The functional regions of the replicase **R** (upper) and mutant **M** (lower). The location of the mutation is indicated by |. Both strings begin with the sequence ‘OBEQBXUTUDYGRHBBOREOLHHHRLUEUOBLROORE’ which is where the binding regions are located. The mutation has the effect of breaking the copy loop.

		Passive			
		<b>R</b>	<b>M</b>	<b>O</b>	<b>S</b>
Active	<b>R</b>	<b>R</b>	<b>M</b>	-	<b>S</b>
	<b>M</b>	<b>O</b>	<b>O</b>	-	<b>O</b>
	<b>O</b>	-	-	-	-
	<b>S</b>	-	-	-	<b>S</b>

Table 2: Interactions of: the replicase **R**; parasitic mutant **M**; product of the mutant **O**; the new strain of replicase that is immune to the parasite **S**. The body of the table shows the outcome of the reaction for each possible combination of active and passive molecules. Where the symbol ‘-’ appears instead of defined molecular species, it denotes no product formed.

parasite. We consider the container to have evaded the parasite when no parasitic molecules (of that strain) remain in the container. Parasite evasion was not originally detected and explained in [10], which is why we now provide an overview of the phenomena. We outline the two mechanisms by which Stringmol containers can survive a parasite and demonstrate that these mechanisms are not available in sticky-Stringmol.

We re-examined previously published Stringmol results [10] and located examples of mid-run parasites that were non-fatal to the container. Here, we give details of one such parasitic molecule and how it interacts with the dominant replicase. We use this example as the basis of our parasite evasion scenario. Figure 5 shows the functional region of the original replicase **R** and the parasitic mutant **M**. The parasite does not implement the loop in the microprogram that allows characters on the bound molecule to be iteratively copied. When the parasite **M** is the executing microprogram, the product of the reaction is **O**, a string of length one: ‘O’.

We examined how the Stringmol container survives this parasite in the original trial [10]. We found a new strain of replicase arose via a mutation in the binding region of **R**. This new strain **S** is never the executing molecule in reactions with **R** or **M** and is thus immune to the parasite, see table 2. The new strain that averts the death of the container, **S**, would have taken over the container via a ‘sweep’, even in the absence of a parasitic mutant as it is always passive when reacting with **R**. In the original trial, both **R** and **M**

Trial condition	No. Escapes
Stringmol	32
Stringmol no mutation	21
Sticky-Stringmol	0
Sticky-Stringmol no mutation:	0

Table 3: Number of escapes from the parasite scenario out of a possible 100 for the four trial conditions.

die out relatively quickly and the new strain becomes dominant. Figure 7 shows results of this scenario depicting typical dynamics of cases where this parasite is fatal and where the system evolves a resistant strain of replicase. Hence the container can sometimes evade what is a potentially fatal parasite.

We investigate the potency of the parasite in Stringmol in order to demonstrate that the parasite is potentially fatal. We also repeat this investigation for sticky-Stringmol and note it is unable to evade the parasite.

Our experimental setup initiates with two string types in the container: A replicase **R** and a parasitic mutant **M** of which there are 300 and 10 respectively at the start of each trial. The container is simulated until no molecules remain or until 0.5 million time steps. In each case we record if the container survived the parasite. We ran 100 trials for each of the four experimental conditions: Stringmol with and without mutation; sticky-Stringmol with and without mutation. The results are presented in table 3.

As we can see from table 3, it is possible for the Stringmol container to evade the parasite without mutation. In the absence of mutation it appears that the probability of binding between **R** and **M** being 0.66 is sufficient for the parasite to not to establish itself in the container in some cases, see figure 8 for typical dynamics. Stringmol (with mutation) is more successful at evading the parasite, see figure 7 for typical dynamics. There are two mechanisms by which the stringmol container can evade a (potentially fatal) parasite. One is by having a relatively low probability of binding, making it hard for new strains to establish themselves in the container. The second mechanism is the potential to mutate to a resistant strain of replicase. Looking at the results in table 3, it would appear that the dominant factor is the 0.66 chance of binding that the replicase, **R**, has with the parasite **M**.

Sticky-Stringmol appears unable to escape this parasite scenario with or without mutation. The ubiquitous binding at probability 1 causes the parasite to dominate the container every time. See figure 6 for dynamics that are typical of sticky-Stringmol both with and without mutation. Mutation in sticky-Stringmol offers no refuge from the parasite molecule. Because the binding is ubiquitous, a parasite is a parasite to all replicase molecules, rather than a limited subset of replicase molecules.

Figure 6: Sticky-Stringmol in the parasite evasion trial. The replicase, **R**, starts at the top at  $t=0$ . The mutant, **M**, starts at  $t=0$  and maintains a low population. The product of the mutation, **O**, peaks in the middle of the run. This figure is representative behaviour of all 200 runs (both with and without mutation).

These results have a bearing on the main point of the paper, the importance on non-trivial binding, which is that it is not only which molecules bind to which that is important. The probability of binding also plays a role in determining the system level properties. Reducing the probability of binding from 1 to 0.66 does not simply cause the same outcome to happen more slowly. This is a refinement on our previous comments and highlights a limitation of our approach to characterizing degeneracy, which requires a boolean understanding of molecular interactions.

## Discussion

Comparing the complexity of the artifacts in sticky-Stringmol with those of Stringmol, we note a loss of many of the more complex artifacts and no additional artifacts. These results demonstrate the importance of binding in AChems. They also indicate the potential for the complexity of a system to be stifled by a single naive component. This leads us to consider what other components of Stringmol (or any AChem) can have their levels of degeneracy measured and increased.

Investigations into the network properties of biological mutation networks, with an eye to how understanding their properties may lead to advances in ALife, are already underway [6]. That study makes use of network analysis techniques; our measure of degeneracy could be added to the array of such techniques. In cases where the sets  $A$  and  $B$  are the same, a binary interaction matrix specifies a network. Network analysis has a concept of ‘structural equivalence’ [15], which is the same as redundancy. The methods of measuring degeneracy and redundancy we introduce are also suitable for systems where  $A \neq B$ , which means they would also be applicable in other fields which do not have a natural mapping to a network, such as the binding of paratopes to epitopes in the immune system [2].

Much of the confusion regarding redundancy and degeneracy stems from the absence of a clear statement of context. A standalone statement of redundancy should take the form: ‘ $a_1$  and  $a_2$  are redundant given  $f$ , and in the context

Figure 7: Stringmol (with mutation) in the parasite evasion trial. In both the upper and lower graphs the seed replicase, **R**, starts at the top at  $t=0$ . The upper graph shows a typical example of the dynamics when the parasite is lethal to the container. The 600 high spike towards the end of the run is the product of the parasite, **O**. The parasite, **M**, peaks at the same time as **O**, but to a height of only 200. The lower graph is an example where mutation gives rise to a new strain of replicase that is immune to the parasite and takes over the container. The 600 high spike is the product of the parasite, **O**. The parasite is fatal to the seed replicase **R**; but at the same time as the parasite and **O** are spiking, a new replicase molecule emerges. Typical Stringmol behavior can be seen for the remainder of the run, with two ‘sweeps’(where the dominant replicase is replaced by a mutation) occurring.

of  $B$ ’. Statements of the truncated form: ‘ $a_1$  and  $a_2$  are redundant’ are ambiguous, relying on the author and reader to have an identical understanding of both  $f$  and  $B$ . Under some alternative criteria,  $f'$  and/or  $B'$ , the elements  $a_1$  and  $a_2$  may well be redundant, degenerate or independent ( $B_{a_1} \cap B_{a_2} = \emptyset$ ). If an author states both  $f$  and  $B$  explicitly, then the context of the redundancy is captured unambiguously. When presented with an ambiguous statement, the best one can do is assume the statement is true and attempt to determine in what context(s) this is the case, as this may give valuable insight.

## Conclusion

We have introduced definitions of degeneracy and redundancy that can be applied to individual examples, such as ‘are two elements degenerate or redundant’, in equations 3 and 4. We have also introduced definitions of degeneracy and redundancy that can be applied when talking about the levels of these properties within a set, in equations 6 and 7. Our measures of degeneracy and redundancy of sets have been defined in such a way that the concept of degeneracy is not conflated with redundancy.

We applied these measures to the binding system used in Stringmol [10][11], demonstrating that the binding sys-

Figure 8: Stringmol without mutation in the parasite evasion trial. In both the upper and lower graphs the seed replicase, **R**, starts at the top at  $t=0$ . The upper graph shows a typical example of the dynamics when the parasite is lethal to the container. The 600 high spike towards the end of the run is the product of the parasite, **O**. The parasite, **M**, peaks at the same time as **O**, but to a height of only 200. The lower graph is an example of the parasitic mutant decaying out of the system, leaving the seed replicase, **R**, unaffected. The parasite **M**, and its product **O**, are present at  $t=0$ , but die out relatively quickly.

tem can produce both degeneracy and redundancy. We hypothesised the importance of a rich binding system to the complexity of the simulation artifacts Stringmol produces. We tested our hypothesis by constructing a deliberately poor Stringmol variant with ubiquitous binding, which we denote as ‘sticky-Stringmol’. Our measures show ubiquitous binding has no degeneracy. Our results demonstrated that a rich binding system facilitates many of the artifacts observed in Stringmol, including: hypercycles (two mutually dependent molecules), macro-mutations (non-point based mutations), sweeps (change of dominant replicase, other than by a random walk) [10], as well as parasite evasion. All of these complex phenomena were lost when we substituted Stringmol’s rich (degenerate) binding system for ubiquitous binding (no degeneracy).

We identified examples of parasite evasion in the previously published results of Stringmol [10], which we used as the basis of a parasite evasion experiment. We compared Stringmol to sticky-Stringmol in this parasite evasion trial, giving an overview of the mechanisms behind the loss of parasite evasion and demonstrating that the difference in binding system was the cause.

Though our hypothesis that ‘degeneracy in the components of an AChem facilitates the complexity of the system as a whole’ has not been proven in general terms, our results support this hypothesis and demonstrate the importance of binding systems in AChems.

# Evolving Three-Dimensional Objects with a Generative Encoding Inspired by Developmental Biology

Jeff Clune<sup>1</sup> and Hod Lipson<sup>1</sup>

<sup>1</sup>Department of Mechanical and Aerospace Engineering, Cornell University  
jeffclune@cornell.edu

## Abstract

This paper introduces an algorithm for evolving 3D objects with a generative encoding that abstracts how biological morphologies are produced. Evolving interesting 3D objects is useful in many disciplines, including artistic design (e.g. sculpture), engineering (e.g. robotics, architecture, or product design), and biology (e.g. for investigating morphological evolution). A critical element in evolving 3D objects is the representation, which strongly influences the types of objects produced. In 2007 a representation was introduced called Compositional Pattern Producing Networks (CPPN), which abstracts how natural phenotypes are generated. To date, however, the ability of CPPNs to create 3D objects has barely been explored. Here we present a new way to create 3D objects with CPPNs. Experiments with both interactive and target-based evolution demonstrate that CPPNs show potential in generating interesting, complex, 3D objects. We further show that changing the information provided to CPPNs and the functions allowed in their genomes biases the types of objects produced. Finally, we validate that the objects transfer well from simulation to the real-world by printing them with a 3D printer. Overall, this paper shows that evolving objects with encodings based on concepts from biological development can be a powerful way to evolve complex, interesting objects, which should be of use in fields as diverse as art, engineering, and biology.

## Motivation and Previous Work

The diversity, complexity, and function of natural morphologies is awe-inspiring. Evolution has created bodies that can fly, run, and swim with amazing agility. It would be desirable to harness the power of evolution to create synthetic physical designs and morphologies. Doing so would benefit a variety of fields. For example, artists, architects and engineers could evolve sculptures, buildings, product designs, and sophisticated robots. Evolution should be especially helpful in the design of complex objects with many interacting parts made of non-linear materials. In such challenging problem domains, evolution excels while human intuition is limited. Being able to evolve sophisticated morphologies also furthers biological research because it enables the investigation of how and why certain natural designs were produced. Evolving 3D objects is thus worthwhile both as a

Figure 1: Examples of evolved objects that were transferred to reality via a 3D printer.

basic science and for its innumerable potential applications. This paper describes how 3D shapes can be evolved and then transferred to reality via 3D printing technology (Figure 1).

Previous research in digital morphological evolution has typically involved encodings that were either highly biologically detailed, or highly-abstract with less biological accuracy. The former camp frequently simulates the low-level processes that govern biological development, such as the diffusing *morphogen* chemicals and proteins that determine the identity of embryonic cells (Bongard and Pfeifer 2001, Eggenberger 1997, Miller 2004). While this approach facilitates studying the mechanisms of developmental biology, the computational cost of simulating chemistry in such detail greatly limits the complexity of the evolved phenotypes. The most complex forms typically evolved in such systems are simple geometric patterns (such as three bands) (Miller

2004) or groups of shapes resembling the earliest stages of animal development (Eggenberger 1997).

The second camp employs high-level abstractions that enable the evolution of more elaborate forms with many parts, but these abstractions tend not to reflect the way that organisms actually develop (Wolpert and Tickle 2010, Bentley 1996). An example is Lindenmayer Systems (L-Systems), which iteratively replace symbols in strings with other symbols until a termination criteria is reached (Lindenmayer 1968, Hornby et al. 2003). While L-Systems can reproduce a wide variety of organismal shapes, especially those of branching plants, they do not model plant developmental processes (Wolpert and Tickle 2010). Another example is the work of Sims (1994), who evolved morphologies that resembled some biological creatures, although with an abstract encoding based on parameterized recursion that does not resemble natural developmental processes (Sims 1994).

A third option is possible, wherein a high-level abstraction is based on the developmental processes that give rise to natural forms. An example of this approach is Compositional Pattern Producing Networks (CPPNs) (Stanley 2007), which are used to evolve 3D objects in this paper and are described in Methods. Two groups have previously evolved 3D objects with CPPNs, although neither conducted an open-ended exploration of 3D objects. One group evolved CPPN objects that were composed of variable-sized spheres and were evaluated on two tasks: falling (Auerbach and Bongard 2010b) or moving rapidly (Auerbach and Bongard 2010a). Most of the evolved forms resembled clubs. A second group evolved soft-bodied robots to move quickly (Hiller and Lipson 2010). These studies demonstrate that CPPNs can create functional shapes, but leave open the question of what types of 3D objects CPPNs can produce with fewer constraints and without specific objectives.

2D pictures are evolved with CPPNs on *picbreeder.org*, where humans perform selection (Secretan et al. 2011). The complexity and natural appearance of the resulting images often support claims regarding the legitimacy of CPPNs as an abstraction of biological development (Stanley 2007). A demonstration in 3D would significantly strengthen these claims, however, because the natural world is 3D. It is possible that CPPNs are unable to frequently make sensible forms with the added difficulty of another dimension, and when objects must be one contiguous unit (which aids in transfers to reality). A recent paper by Bánsági Jr et al. (*Science* 2011) highlights the need to verify that generative encodings that produce complex patterns in 2D also can do so in 3D. By evolving CPPN objects in the natural 3D setting, this paper conducts a critical test of the hypothesis that generative encodings based on *geometric* abstractions of development capture some of the complexity-generating power of natural morphological development. Doing so also provides a visually intuitive testbed for studying how variants of such generative encodings behave. It also reveals the utility of

CPPNs as a representation for 3D object design.

## Methods

### Compositional Pattern Producing Networks

Compositional Pattern Producing Networks (CPPNs) abstract the process of natural development without simulating the low-level chemical dynamics involved in developmental biology (Stanley 2007). Cells (and higher-level modules) in natural organisms often differentiate into their possible types (e.g. heart or spleen) as a function of where they are situated in geometric space (Wolpert and Tickle 2010).

Components of natural organisms cannot directly determine their geometric location, so developmental processes have evolved to create gradients of chemicals and proteins called morphogens that organismal components use to figure out *where* they are and, thus, *what* to become (Wolpert and Tickle 2010). For example, in many animals the anterior-posterior and dorsal-ventral axes are specified by maternally provided morphogen gradients. Embryonic genes then construct more complicated geometric patterns of morphogens as a function of these simpler gradients. Downstream genes can construct additional pattern as a function of any of the patterns already created, enabling the production of patterns of arbitrary complexity (Wolpert and Tickle 2010).

CPPNs abstract this process by allowing similar geometric patterns to be composed of other geometric patterns, but represent the patterns mathematically instead of via diffusing morphogens. To replace maternally-provided gradients, the experimenter provides the initial gradients. Final patterns output by the CPPN determine the attributes of the phenotypic components at different geometric locations. For example, two-dimensional pictures could be encoded by iteratively passing the coordinates of each pixel on a canvas (e.g.  $x = 2, y = 4$ ) to a CPPN genome and having the output specify the color or shade of each pixel (Figure 2).

Each CPPN is a directed graph in which every node is itself a single function, such as sine or Gaussian. The nature of the functions can create a wide variety of desirable properties, such as symmetry (e.g. a Gaussian function) and repetition (e.g. a sine function) that evolution can exploit. Because the genome allows functions to be made of other functions, coordinate frames can be combined. For instance, a sine function early in the network can create a repeating theme that, when passed into the symmetrical Gaussian function, creates a repeating series of symmetrical motifs (Figure 2). This process abstracts the natural developmental processes described above (Wolpert and Tickle 2010).

The links that connect and allow information to flow between nodes in a CPPN have a weight that can magnify or diminish the values that pass along them. Mutations that change these weights may, for example, give a stronger influence to a symmetry-generating part of a network while diminishing the contribution from another part.

Figure 2: CPPNs combine mathematical functions to create regularities, such as symmetries and repeated modules, with and without variation. Adapted from Stanley (2007).

Variation is produced by mutating or crossing CPPNs. Mutations can add a node or change weights. The default set of allowable functions for CPPNs in this paper are sine, sigmoid, Gaussian, and linear, although we also experimented with additional functions (see Results). The evolution of the population of CPPN networks occurs according to the principles of the NeuroEvolution of Augmenting Topologies (NEAT) algorithm (Stanley and Miikkulainen 2002).

The NEAT algorithm contains three major components (Stanley and Miikkulainen 2002). (1) It starts with small genomes that encode simple networks and complexifies them via mutations that add nodes and links to the network. This complexification enables the algorithm to evolve the network topology in addition to its weights. (2) NEAT preserves diversity via a fitness-sharing mechanism that allows new innovations time to be tuned by evolution before competing them against more optimized rivals. (3) crossover utilizes historical information in a way that is effective, yet avoids the need for expensive topological analysis.

### Encoding 3D Objects with CPPNs

To evolve 3D objects, inputs for the  $x$ ,  $y$ , and  $z$  dimensions are provided to a CPPN. Additional gradients can be provided, which may bias the types of objects produced (see Results). A *workspace* (maximum object size) is defined with a *resolution*, which determines the number of voxels in each dimension. In this paper there are 10 voxels in the  $x$  and  $z$  dimensions and 20 in the  $y$  (vertical) dimension. The  $x$ ,  $y$ , and  $z$  value of each voxel are iteratively input to a CPPN, and voxels are considered full if the CPPN output is greater than a threshold (here set to 0.1), otherwise the voxel is considered empty. The 3D voxel array is then processed by the surface-smoothing Marching Cubes algorithm (Lorenson and Cline 1987). A normal is provided for each vertex when visualizing the objects in OpenGL, a graphics technique that further smooths the surface. These two smoothing steps en-

able high-resolution CPPN objects to be visualized without prohibitive computational costs.

This algorithm for encoding 3D objects is a more straightforward extension of how CPPNs encode 2D pictures (Stanley 2007, Secretan et al. 2011) than another algorithm for evolving 3D objects with CPPNs, which included growth over time and limited shapes to collections of attached spheres of different sizes (Auerbach and Bongard 2010b;a).

### Selection Mechanisms (Fitness Assignment)

We evolve images with interactive evolution and target-based evolution. During interactive evolution the user (here, the first author) views  $N$  rotating objects (here, 15) and selects a champion, which receives a fitness of 1000. The user can also reward additional organisms that receive a fitness of 500. To avoid uninteresting objects, those that are not chosen, yet have voxel counts between 10% and 90% of the maximum number possible, are given a fitness of 100. The remaining objects are given a fitness of 1. For target evolution, the fitness is the percent of voxels that matched the target object. To magnify differences in fitness values, all fitness scores serve as an exponent to a large constant  $c = 2000$  to produce the final fitness value. The parameters are identical to a previous work (Clune et al. 2011), except mutations were allowed to be larger (MutationPower = 2.5).

## Results and Discussion

### Interactive Evolution

**Overall summary** We study interactive evolution because it allows an open-ended exploration of the design space of objects CPPNs can produce. Additionally, interactive evolution avoids the greedy nature of target-based evolution, potentially allowing it to access more interesting objects (Secretan et al. 2011, Lehman and Stanley 2008). A drawback of interactive evolution is that it is subjective, but science should not abandon such a useful tool simply because it is subjective. While user preferences bias the types of objects selected, the encoding has to be able to produce such objects in the first place in order for them to be selected. Different encodings will bias the types of patterns evolved (Clune et al. 2011), meaning that interactive evolution can inform us about the biases and expressive power of the encoding.

Figure 3 shows example objects from different generations during a run of interactive evolution. The geometric patterns become more complex over generations, which reflects the property of complexification built into NEAT (Stanley and Miikkulainen 2002).

Figure 4 displays a few of the interesting objects discovered in different runs, some of which had different inputs and parameters (described below). It is important to note that these objects were chosen from a small number of runs performed by one person, each of which was limited to tens or perhaps a few hundred generations. It is noteworthy that such recognizable 3D forms emerge in such a

Figure 3: Representative objects from different generations of a single run of interactive evolution. From top to bottom, rows display individuals from generations 1, 15, and 33.

small sample size. These 3D objects should not be held to the same standard as pictures from *picbreeder.org*, where hundreds of users have published thousands of images after performing over 150,000 evaluations across hundreds of generations (Secretan et al. 2011).

The objects in Figure 4 exhibit many properties that are desirable both for studying morphological evolution and harnessing it for engineering or artistic purposes. The objects are frequently regular, a property which is important in engineering and for evolvability (Lipson 2007, Clune et al. 2011). An important regularity is symmetry, which is evident with respect to different dimensions in many of the objects. For example, all of the objects in generation 33 of Figure 3 are highly left-right symmetric, and objects b7 and b8 in Figure 4 exhibit left-right and top-bottom symmetries. Another useful regularity is repetition, which occurs frequently in the evolved objects (e.g. the top-right object in Figure 3). A further beneficial property is exhibiting regularity with variation (Stanley and Miikkulainen 2003, Lipson 2007, Clune et al. 2011). For example, Figure 4b1 has a motif that appears like an animal head, but is repeated in different sizes and with other subtle variations. Symmetric patterns with asymmetric variations can also be observed, such as in Figure 4a8 and Figure 4b6.

It is important to note that humans often select regular, symmetrical shapes, which increases their frequency in interactive evolution. That said, biology and engineering also often reward regularity. Additionally, it has been shown that when CPPNs generate artificial neural networks that control robots in target-based evolution, the neural wiring patterns are often regular, including symmetries and repeated themes (Clune et al. 2011), demonstrating that CPPNs produce regularities even without humans performing selection.

Most importantly, the evolved objects often look similar to natural forms or engineered designs, revealing that CPPNs can produce the types of objects we are interested in designing and studying with synthetic morphological evolution. Humans can only select such familiar forms if an encoding tends to produce such designs, which has not been the case for most previous generative encodings. People often describe Figure 4a2 and 4a3 as faces, 4a4 as a Jack-o'-lantern face, 4a5 as an animal figurine, 4a6 as an African statue of a human, 4a7 as a human female stomach, 4a8 as a human female torso, 4b1 and 4b4 as animals, 4b2 and 4b3 as elephants, 4b5 as a human head and shoulders, 4b6 as a horned mask, and 4b7 and 4b8 as spaceships. Some also describe 4b7 as a butterfly. People describe other objects as interesting art, even though they do not resemble any specific natural or human design (e.g. Figure 4a1). Such objects can potentially spark artistic ideas for new forms. The fact that the shapes consistently evoke human and natural designs demonstrates the expressive power of the CPPN encoding to produce interesting 3D objects.

An additional important property is that the offspring of the 3D CPPN objects are similar to their parents, but are varied in interesting ways. Some encodings lack this property in that mutations have dramatic effects, rendering most offspring very different from their parents, which hinders evolvability (Stanley and Miikkulainen 2003). For example, Figure 4b4 is the child of Figure 4b3, and Figure 4b2 is their close relative. All three are consistently described as animals, yet are interesting variations on the animal theme. For example, only a single generation of genetic changes between Figure 4b3 and Figure 4b4 transformed what appears like an elephant with a trunk into something resembling an elephant with warthog tusks. A different variant of Figure 4b3 that thickened the trunk can be seen in Figure 1 (center row, left), which is next to a printed copy of Figure 4b3. Moreover, Figure 4b3, its relative in Figure 1, and Figure 4b2 all evoke elephants, but they are quite different objects, suggesting that the CPPN has captured some fundamental aspects of the elephant concept that it expresses in different ways.

Some of the geometric complexity in the genome is not visible in these 3D phenotypes because a threshold determines the presence or absence of a voxel. In contrast, *picbreeder* pictures have a continuum of outputs in grayscale and color, which adds to their complexity. Pre-thresholded geometric information could be useful, however, to make colored 3D objects, or to have objects with multiple materials (e.g. the soft-robot equivalent of muscle and bone).

### Varying CPPN parameters generates different objects

To test whether the types of objects produced could be biased by the CPPN inputs and parameters, we performed multiple runs of interactive evolution with varying conditions. We initially provided only  $x$ ,  $y$ , and  $z$  values for

Figure 4: Example objects evolved with CPPNs via interactive evolution.

each voxel. Even with this minimal information, regularities such as symmetries and repeating themes were common (Figure 3), which is expected in a generative encoding with symmetric and repeating genomic functions. The objects in this setup seemed to require more generations before they became interesting, and usually did not appear like objects floating in space, but instead bordered the workspace wall.

We then added the distance from center as an input to the CPPN, which picbreeder also has (in 2D) (Secretan et al. 2011). This information more frequently created rounded objects centered in space. Because the distance-from-center function took the normalized values in each dimension, and the  $y$  (height) dimension was longer, an egg-shaped motif was common (Figure 5, left three). All of the objects in Figure 4 have this input. Preliminary experiments with other inputs also revealed interesting biases in the resulting objects (not shown), suggesting a rich area of research regarding how best to bias CPPNs with seed gradients.

To date, no published results explore how patterns differ when recurrence is allowed in CPPN genomes. We enabled recurrence and discovered that the resulting patterns are qualitatively different in that they tend to include fractal patterns. For example, branching patterns emerged, such as an object resembling a tree (Figure 6, left) and another evoking the vascular system (Figure 6, center). Like with fractals, the complexity is often concentrated at the surface boundary, producing a jagged surface effect (e.g. Figure 6, right). Objects with recurrent genomes were much more likely to have small, separated pieces floating in space.

Another interesting parameter of CPPNs is the set of possible genomic node functions. No research published to date has tested different function sets on the same problem to understand how CPPN patterns are affected by this pa-

Figure 5: Objects evolved with a distance-from-center input (left three), which frequently featured egg-shape motifs, and objects evolved with an expanded set of genome functions (right three). The rightmost two images show different angles of the same object. Facets in the right three objects result from a close zoom and because, for illustration, normals are provided for facets instead of vertices.

rameter. Visual domains such as 3D objects are a helpful place to start such explorations because of the intuition they provide. We added a square, cosine, and sign-preserving square root function and performed additional runs. Objects in these runs tend to be more complex in earlier generations, and seem to involve both rounded and sharp edges. Figure 4b7 and the rightmost three in Figure 5 are example objects evolved with this expanded genomic node function set.

### Target-based Evolution

A second way to explore the capabilities of CPPNs is to challenge them to produce a target object. Knowing how CPPNs perform in 3D in target-based evolution is helpful for numerous reasons. Initially, it serves as a preliminary test of how CPPNs might perform on more open-ended, yet still target-based problems, such as evolving robot morphologies to perform certain tasks (e.g. locomotion). Additionally, biologists would benefit if they could repeatedly evolve var-

Figure 6: Example objects with recurrent genomes.

ious morphologies to study whether certain developmental strategies for constructing 3D geometric patterns arise frequently. Finally, target evolution allows an artist or engineer to explore objects that are similar to a target object, yet differ in interesting ways (similar to how Figure 4b4 and Figure 4b2 result from slight permutations to the genome of Figure 4b3). Finally, target-based evolution is much faster, enabling an exploration the effects of different parameter settings, which can inform interactive evolution.

The target object for this paper is shown in Figure 8a. It consists of four partially-overlapping spheres, with the outer two halved by workspace bounding box. This target has round shapes that are different from the egg-shaped motif facilitated by the distance-from-center input, providing a test of whether such a related input improves performance. Each treatment has 20 runs with a population of 150 for 1000 generations, unless otherwise specified.

The baseline treatment featured only  $x$ ,  $y$ , and  $z$  inputs and the default set of genome functions. The best performing object in each run captures the long cylindrical shape of the target, but most attempts at rounded edges are imperfect combinations of straight-line functions. All runs except one failed to carve much material away between the spheres. An average of 90.8% ( $\pm 0.003$  SE) of voxels are matched (Figure 7), but the target object is not identifiable until about  $\geq 93\%$  of voxels are matched. As such, the small differences in fitness between the treatments in Figure 7 represent substantial differences in whether the target object is recognizable. Interestingly, one outlier run in this treatment performed much better than the rest (with 94.6% of voxels correct). It features rectangular approximations of spheres (Figure 8b). The lack of round shapes in this treatment corroborates the previous subjective observation from interactive evolution that CPPNs can struggle to evolve and exploit round gradients when they are not provided as inputs.

To test if seeding CPPNs with spherical gradients makes it easier to match this rounded target, we added distance to the center as an input. The CPPNs in the previous treatment

could have evolved to calculate this same information, but that may have been difficult. Surprisingly, this information significantly lowered performance to 90.0% ( $\pm 0.002$  SE,  $p = 0.013$ , Mann-Whitney test, Figure 7). However, the evolved objects all have smooth, round forms (Figure 8c-d), confirming that providing different seed gradients can bias the types of evolved objects. While this might be expected in early generations, it is interesting that the gradients provided have noticeable effects after a thousand generations. This result is in line with a previous paper that found that the information input into CPPNs can bias the resulting phenotypes (Clune et al. 2009). We include this input in the remaining treatments in this paper because it facilitates round surfaces, even though it hurt performance in this experiment.

Because interactive evolution features smaller population sizes, it is worthwhile to study how this difference affects the search for 3D objects. Additionally, since NEAT complexifies genomes over evolutionary time, having more generations may improve the search by accessing genomes with more hidden nodes. We investigate these issues by decreasing the population size from 150 to 15 and increasing the number of generations tenfold to  $10^4$ , which keeps the number of evaluated objects the same. This change significantly improves performance to 91.8% ( $\pm 0.003$  SE,  $p < 0.001$ , Mann-Whitney test, Figure 7), suggesting that the small population sizes in interactive evolution do not hurt, and may actually benefit, morphological evolution with NEAT-based encodings. The evolved objects tend to have more space carved out between the spheres (Figure 8e-f).

A fundamental evolutionary parameter that can greatly affect evolvability is the mutation rate. We varied the major sources of mutation in NEAT by altering the rate at which genomic links are added, removed, and mutated, as well as the rate at which genomic nodes are added. Increasing the node addition rate significantly boosted performance ( $p < 0.001$ , Mann-Whitney test, Figure 7) to 91.5% ( $\pm 0.003$  SE). Changing the other mutation rate parameters did

Figure 7: Means of the best-performing individuals for target-based evolution. See text for variance.

Figure 8: Target-based evolution objects.

not improve performance (data not shown).

Because a smaller population with more generations was beneficial, and because a higher mutation rate was beneficial, we tested whether both changes together would outperform either alone. The combination did improve performance to 92.0% (Figure 7), but the difference was not significant ( $p > 0.05$ , Mann-Whitney test). We also found that the expanded genome function set (described previously) improved performance to 93.0%, which was significant ( $p = 0.022$ , Mann-Whitney test). As before, the objects in this treatment seemed to combine rounded surfaces with sharper edges: while most were smooth (e.g. Figure 8g-h), a few had rough patches on their surface, including Figure 8i. Adding recurrent genomic connections to this treatment did not significantly affect performance (93.3%,  $p > 0.05$ ).

Overall, the target-based evolution experiments reveal that evolving CPPNs can roughly match a target object. While a high percentage of voxels were matched, the degree to which the evolved objects qualitatively resemble the target is subjective and debatable. The most important contribution of these experiments is to better understand the way in which target-based evolution is biased by different parameters. These results are preliminary, however, until more tests can be conducted with additional targets.

It is also interesting that many of the evolved objects look designed for a purpose. For example, many of the objects in Figure 8 seem like functional and aesthetically attractive objects carved on a lathe, such as legs from tables and chairs or posts from banisters and railings. One reason this is surprising is because it could have been the case that the greedy nature of target-based evolution would have gained improvements by iteratively adding small patches of voxels that match a subset of the overall space. Such a patchwork solution would not look as regular and smooth as the objects that actually evolved, suggesting that CPPNs are bi-

ased away from such a piecemeal strategy. Previous work has shown that CPPNs have difficulty making exceptions to regular patterns when evolving neural networks (Clune et al. 2011), which could explain why the target object in this study was not matched one patch at a time. Such a bias toward regularity may simultaneously explain the smoothness of the evolved objects and why matching the final few percent of voxels is so difficult.

Artists and engineers may actually benefit from the fact that the evolved objects share some properties of the target, but are different in interesting ways. This means that a designer can provide a seed object as a target, and a series of objects can automatically be generated that are aesthetically interesting variations on that seed concept (Figure 8).

## Transferring Objects to the Physical World

Advances in 3D printing technologies make it possible to transfer evolved objects into the physical world, which may help artists and engineers benefit from this technology. To test whether CPPN objects maintained their appearance and structural integrity in reality we printed them on a Connex500 3D printer. The objects look similar to their simulated counterparts and are structurally sound (Figure 1). One difference is that non-contiguous pieces (e.g. the top of Figure 6, left) are not held in place in the physical world without additional scaffolding. By printing in a semi-transparent material, we also discovered that none of the objects have visible hollow areas embedded within them, although CPPNs can create such negative spaces. While the gap between simulated and physical objects was not expected to be large for static objects, it is helpful to have verified the fidelity of the transfer.

## Conclusions and Future Work

This paper introduces an algorithm for evolving 3D objects with the CPPN generative encoding, which is a computationally efficient abstraction of biological development. We conducted both interactive and target-based evolution to explore the ability of CPPNs to create complex objects, especially those that resemble natural and engineered designs.

A small, preliminary exploration of the design space of 3D CPPN objects unearthed a diversity of objects that evoke natural and engineered forms. Many of the objects featured regularities such as symmetry and repetition, with and without variation. Such properties are important for engineering and evolvability (Lipson 2007, Clune et al. 2011), and suggest that CPPNs are a promising encoding for evolving useful and aesthetically pleasing objects. To extend this research we are creating a website like picbreeder.org (Secretan et al. 2011) where users can collaboratively evolve 3D objects online, which will provide a much larger exploration of the potential of this technology. It will also overcome the need for any individual to perform all of the evaluations in a lineage and thus allow more complex objects to evolve.

Experiments with target-based evolution on one target revealed how the inputs and parameters of CPPNs can influence the types of objects they evolve. The evolved objects roughly resemble the target, but do not match it precisely. While the evolved objects share some properties of the target, they also differ from it in interesting ways. This property could help artists and engineers by providing 3D designs that are variations on a seed concept. All of these conclusions are tentative, however, since experiments were only conducted with one target. Future work is necessary to determine whether these observations generalize.

While there are many useful applications for evolving static, single-material 3D objects, this technology is also a stepping stone to evolving objects that can move and that have multiple materials. In future work we will evolve such soft-bodied robots in simulation and transfer them to the physical world. Doing so will enable us to harness the power of evolution and developmental biology to begin to create synthetic creatures that have some of the exciting properties of their natural counterparts.

## Abstract

Kin selection theory predicts that evolution favors altruist genes that are more accurate in targeting altruism only to copies of themselves. We support this prediction by competing multiple altruist-targeting mechanisms that vary in accuracy in determining if a recipient carries a copy of the altruist gene. We compete altruism-targeting mechanisms that make energy donations based on (1) kinship (kin targeting), (2) genetic similarity at a level greater than expected for kin (similarity targeting), and (3) perfect knowledge of the presence of an altruist gene (Green Beard targeting). Natural selection favored the most accurate targeting mechanism available, once altruism *levels* were accounted for (Fig. 1). Our investigations also revealed that the Green Beard mechanism, originally invented as a hypothetical example of a perfectly accurate, cheater-proof system and subsequently discovered in nature, is in fact vulnerable to cheaters. Such cheaters prevent Green Beard targeting from outcompeting kin and similarity targeting (Fig. 1c). The reason is because Green Beard altruists donate to organisms that have Green Beards and make *at least one* Green Beard donation. There is thus an evolutionary pressure to donate only once, thereby qualifying to receive Green Beard donations while paying as little as possible. By increasing the number of donations necessary to *qualify* to receive Green Beard donations ( $T$ ), we showed that organisms evolved to donate just above this threshold (Fig. 2). Green Beard targeting could only take advantage of its increased accuracy and outcompete kin and similarity targeting when we artificially set  $T$  to a high number, such as 100 (Fig. 1d). These results raise the question of how kin and similarity targeting differ from Green Beard targeting in being able to raise altruism levels despite the presence of cheaters. The answer is that they have built-in mechanisms that keep cheaters at bay (Fig. 3). We propose that Green Beard targeting can be augmented with a similar defense against cheaters if mutations that change the altruism level also change the marker (e.g., beard color), such that beard color reliably indicates the altruism level. This *Identical Beard Color* mechanism raises its altruism level automatically and outcompetes kin and similarity targeting due to better accuracy (Fig. 1e). Overall, our results confirm that natural selection favors altruist genes that are increasingly accurate in targeting altruism to only their copies. Our work also emphasizes that the concept of targeting accuracy must include both the presence of an altruist gene and the *level* of altruism it produces.

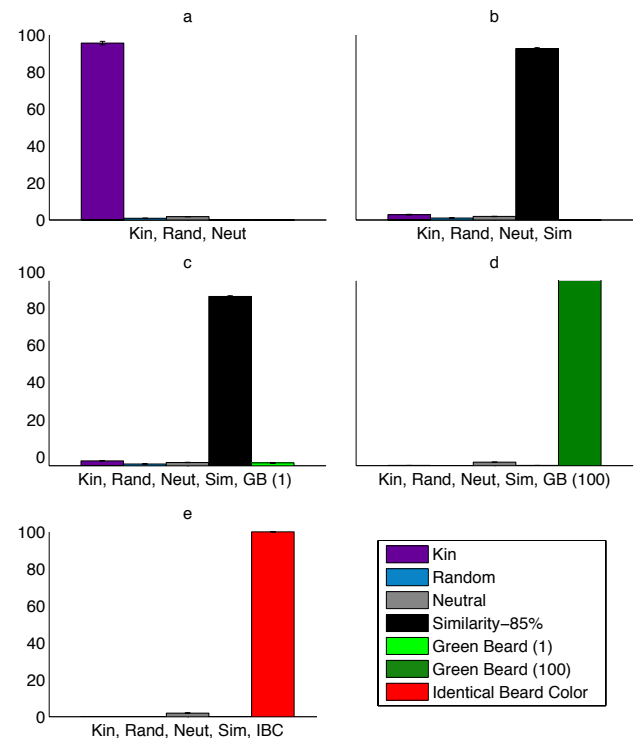

Figure 1: Evolved altruism levels for different targeting mechanisms. Plotted is the average number of donations made by last-generation organisms in 50 trials ( $\pm$  one standard error, often too small to distinguish). The maximum number of donations is capped at 100. (a) Targeting altruism based on kinship was selected for over two controls (targeting altruism at random, and a neutral instruction). (b) Targeting altruism based on high genetic similarity was favored over targeting based on kinship. (c) Selection did not favor targeting altruism via a Green Beard mechanism (with a threshold of 1) over kin and similarity targeting. (d) Selection favored a Green Beard mechanism with a threshold of 100 (the maximum number of donations allowed) over kin and similarity targeting. (e) Selection favors Identical Beard Color targeting over kin and similarity targeting.

\*Published in Proc. Royal Society, 2011, 278(1706): 666-674.

Figure 2: Evolved altruism levels for different Green Beard thresholds. Plotted is the average number of donations made per organism for different threshold values ( $T$ ) of the donate-threshold-gb instruction (averaged from the final populations of 50 trials per treatment  $\pm$  one standard error, often too small to distinguish). Organisms evolved to perform enough donations to surpass the threshold and thus qualify to receive altruism, but did not perform substantially more than  $T$  donations.

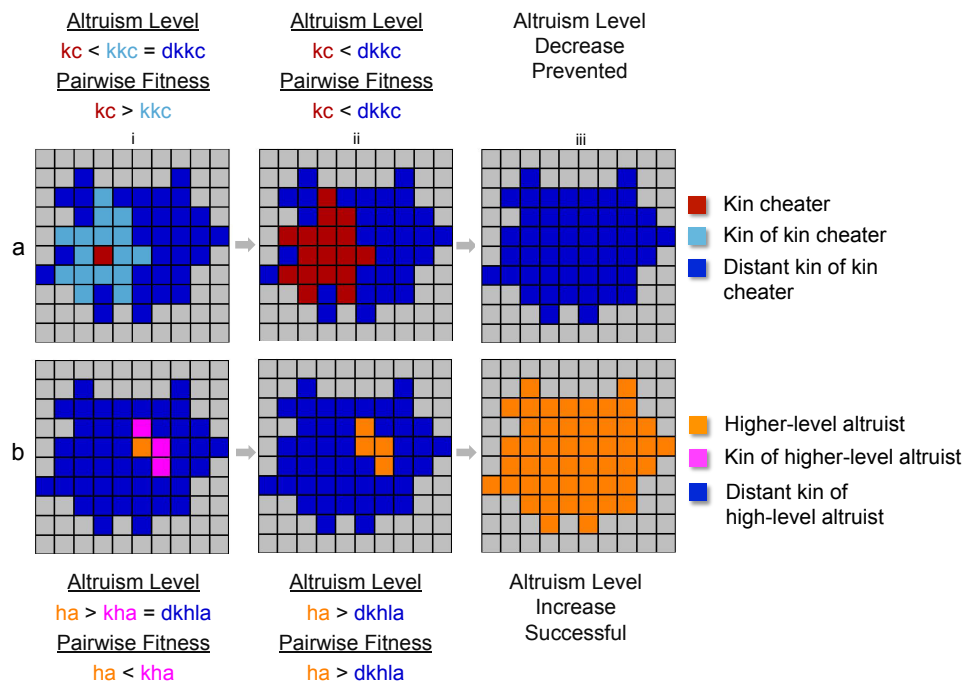

Figure 3: How kin and similarity targeting can evolve persistently high altruism levels. A thought experiment illustration showing how (a) kin-based altruism naturally thwarts kin-cheaters and (b) enables enduring increases in altruism levels. (a-i) Consider a group of related organisms that are altruistic to each other (blue and light-blue). One organism may mutate to be less altruistic, becoming a kin-cheater (red), but since only its closest relatives (light-blue) will consider it kin, only they will be altruistic toward it. (a-ii) The kin-cheater will tend to supplant its kin because it receives more donations from them than it gives. (a-iii) Once the kin-cheater has replaced those that considered it kin, the kin-cheater is left receiving donations only from other kin-cheaters. This group (red) will have a lower altruism level than their distant kin (blue) and will come to be replaced by them. (b-i) Now consider an organism (orange) that mutates to have a higher level of altruism than its ancestors (blue). Initially, it will be selected against because it gives more donations to those that it considers kin (pink) than it receives from them. (b-ii) If the less-altruistic kin of the higher-level altruist are killed off by drift, then the higher-level altruist and its offspring (orange) will have a competitive advantage over their distant ancestors (blue). (b-iii) While chance is required to start the process, once it has occurred there will be selection for the higher level of altruism. There are additional factors that complicate all of these fitness comparisons, but for clarity we have sketched these scenarios only in broad strokes.

# Natural Selection Fails to Optimize Mutation Rates for Long-Term Adaptation on Rugged Fitness Landscapes\*

## Abstract

The rate of mutation is central to evolution. Mutations are required for adaptation, yet most mutations with phenotypic effects are deleterious. As a consequence, the mutation rate that maximizes adaptation will be some intermediate value. This abstract summarizes a previous publication in which we used Avida, a well-studied artificial life platform, to investigate the ability of natural selection to adjust and optimize mutation rates. Our initial experiments occurred in a previously studied environment with a complex fitness landscape (Lenski et al. *Nature*, 423, 2003) where Avidians were rewarded for performing any of nine logic tasks. We assessed the optimal mutation rate by empirically determining which unchanging mutation rate produced the highest rate of adaptation. Then, we allowed mutation rates to evolve and we evaluated their proximity to the optimum. Although we chose conditions favorable for mutation rate optimization (asexual organisms not yet adapted to a new environment), the evolved rates were invariably far below the optimum across a wide range of experimental parameter settings (Fig. 1). We hypothesized that the reason mutation rates evolved to be suboptimal was the ruggedness of fitness landscapes. To test this hypothesis, we created a simplified ‘counting ones’ (a.k.a. ‘onemax’) landscape without any fitness valleys and found that, in such conditions, populations evolved near-optimal mutation rates (Fig. 2, top row). In contrast, once moderate fitness valleys were added to this simple landscape, the ability of evolving populations to find the optimal mutation rate was lost (Fig. 2, bottom two rows). Additional experiments revealed that lowering the rate at which mutation rates evolved did not preclude the evolution of suboptimal mutation rates (see original manuscript). We conclude that rugged fitness landscapes can prevent the evolution of mutation rates that are optimal for long-term adaptation because of the short-term costs of traversing fitness valleys. This finding has important implications for evolutionary research in both biological and computational realms.

\*Published in PLoS Computational Biology, 2008, 4(9).

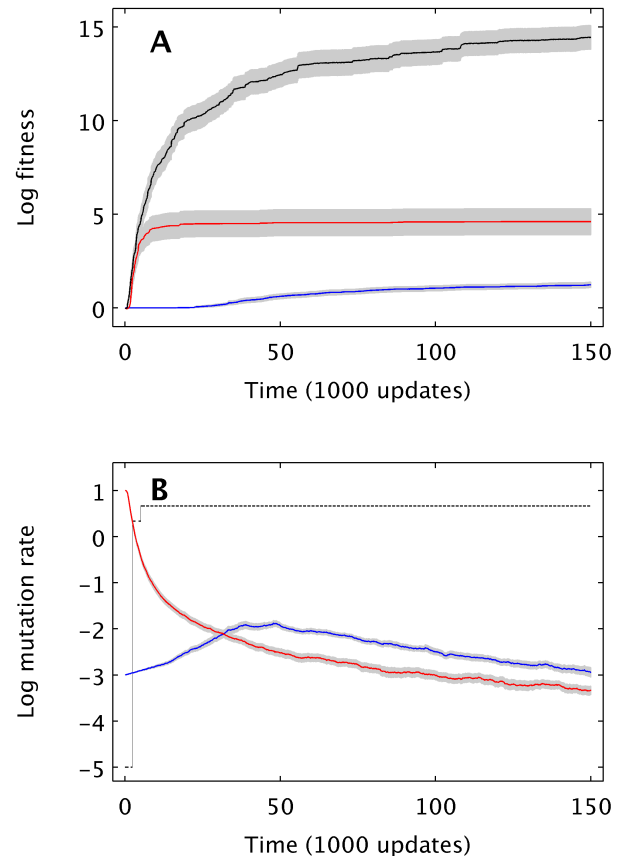

Figure 1: Evolutionary trajectories for fitness and mutation rate on a complex fitness landscape reveal that evolved mutation rates are lower and produce less adaptation (lower fitness values) than a certain (long-term optimal) non-evolving rate. (A) Evolution of average (over 50 runs) log-fitness  $\pm 1$  s.e.m. for treatments with the genomic mutation rate fixed at the empirically determined optimum rate  $U_{opt} = 4.641$  (black) and for treatments with variable, evolving genomic mutation rates starting at either 10 (red) or  $10^{-3}$  (blue). (B) Evolution of average log genomic mutation rate  $\pm 1$  s.e.m. for treatments with variable, evolving mutation rates starting at either 10 (red) or  $10^{-3}$  (blue). The black line indicates the mutation rate that had produced the highest average fitness for that time point.

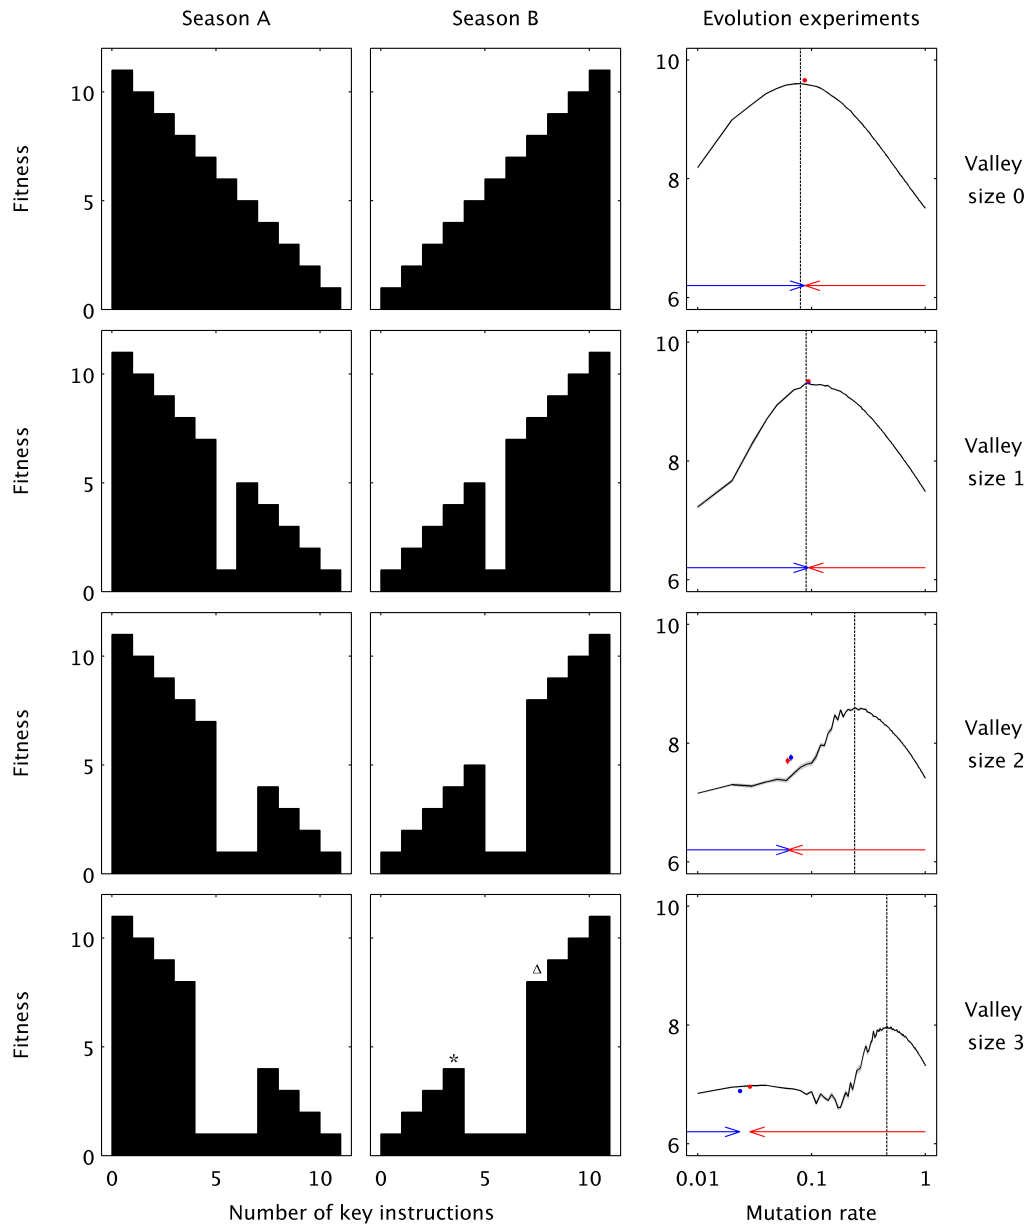

Figure 2: Evolution of mutation rates on simple fitness landscapes with different ruggedness. Here, fitness depended solely on the match between the environment and the number of a key instruction that organisms had in their genomes. In season A (left column) the key instruction was deleterious while it was beneficial in season B (center column). Rugged fitness landscapes with maladaptive valleys (rows 2-4) were introduced by setting the fitness of organisms with intermediate numbers of the key instruction to the minimum fitness level of one. The right-most column shows the results of evolution experiments under each of these selective regimes. Final fitness is shown as a function of genomic mutation rate for both static and dynamic mutation rates. The solid black line represents the average of the mean fitness across 10 runs for each of 100 different static mutation rates ranging from  $U = 0.01$  to 1 in increments of 0.01. The two colored points represent the mean fitness and mutation rate, both averaged over 50 runs where the mutation rate freely evolved, with initial rates of  $U = 1$  (red) or  $10^{-5}$  (blue). Mutation rate and fitness values were time-averaged over the last 10 of 50 environmental changes. Owing to very similar final values, despite the very large initial differences, the individual colored points are indistinguishable in the first two rows, and error bars are not visible. The arrows indicate where mutation rates began and ended, on average, for the dynamic-rate experiments. Although the optimal mutation rate increases as a function of valley size (note the right-shift in the dashed line from top to bottom), the evolved mutation rates in fact decrease as a function of valley size (note the left-shift of the blue and red points from top to bottom).

# Recovering Hidden Swarm Parameters Using a Simulated “Robofish”

## Abstract

Swarming is behaviour which emerges from the action of individual agents. Models of swarm behaviour impose fixed model parameters on the agents comprising the swarm. This paper evaluates the possibility of extracting the parameters of a swarm model from the swarm. This can be achieved by evolving the parameters of a single agent that interacts with the swarm. The approach was inspired by work on so-called “robofish” by Faria et al. If we assume that the collective dynamics of wild animals can be modelled, it would be desirable to recover the dynamics of the model via interaction with them. We demonstrate that it is possible to recover the parameters of a shoaling model used by a swarm. We present an evaluation of this approach, using a genetic algorithm to drive the learning process. The experiments also reveal information about the effects of varying the parameters of the model on the emergent swarm dynamics.

## Introduction

In nature many animals travel in flocks, shoals, swarms and other large groups. Several models have been proposed to replicate this phenomena (Aoki, 1982; Reynolds, 1987; Couzin et al., 2002). In each of these models, individuals follow local rules which produce the swarm as an emergent phenomenon. However little work has been done to find out the validity of these models and how accurately they map to behaviour in real-world swarms. In this paper we explore this possibility by investigating whether an agent can recover the parameters of a swarm by monitoring its interactions with the rest of the swarm. We test an evolutionary approach to this learning problem. If the evolved behaviour of the agent and swarm is identical then the models used by them are functionally equivalent. This novel approach was inspired by the work of Faria et al. (2010), in which a robotic fish (or *robofish*) interacts with a shoal of sticklebacks *Gasterosteus aculeatus* L. We refer to the shoal of fish with which the robofish interacts as the *modelfish* in the rest of this paper, since it is presumed that the shoal is following a model of behaviour which the researcher is trying to discover. This paper extends the work presented in (Coates and Hickinbotham, 2011).

It is only possible to determine whether model parameters can be learned in this way if the parameters of the swarm are known. Accordingly, we test the approach in simulation, where a swarm of modelfish follow a pre-specified model. In addition, the fitness function which is used to evolve the robofish model only makes use of observations about the emergent behaviour of the swarm. In other words, the model parameters are “hidden” from the evolutionary algorithm.

Aoki (1982) described one of the first attempts to accurately model the behaviour of fish. The behaviour of each fish is determined by the position of its neighbors. The space around the fish is divided into zones of perception relative to the position and orientation of the fish. Each zone has a corresponding behaviour linked to it, commonly called a *compulsion*. The presence of fish in a particular zone increases the contribution of the compulsion to the behaviour of the fish in the next discrete time step. In Aoki’s model, the fish’s area of perception is split into three radii. Behind the fish there is also a “blind spot”, the contents of which do not contribute to the fish’s behaviour. Nearest the fish is the zone of repulsion, then comes the zone of orientation and finally the zone of attraction. Aoki’s model only takes into account up to four neighboring fish in the zone of perception. These are selected randomly (with a greater chance of choosing those in front) and have a diminishing effect of the movement of the fish. If no neighbours are found in the zone of perception, the fish will try and move towards any it can see, no matter the distance. The neighbours it finds (and the zones they appear in) change the mean and standard variation of a Gaussian model which governs the update of the heading of the fish.

Swarm simulations were originally developed to study the behaviour of real animals. They were used to provide insights into possible reasons for why swarms behave as they do and how changing the simulations parameters affects the resulting behaviour. Since then they have found uses in computer graphics (Reynolds, 1987), as well as in searching data (Kennedy and Eberhart, 1995). Reynolds (1987) developed one of the best known swarm models, designed not necessarily to be authentic but to give aesthetically pleasing move-

Figure 1: The three zones of the 2D Couzin model. The orientation of the fish is shown by a bold arrow (centre). The blind spot is shown as a shaded area. The widths of the zones of Attraction (ZOA), Orientation (ZOO) and Repulsion (ZOR) are indicated by arrows. Note that the position of the outer zones relative to the fish are dependent upon the widths of the inner zones.

ment for animation purposes. It consists of a single zone of perception within which a “boid” is able to detect others. Its movement is also governed by three compulsions with regards to the neighbours it can see, the urge to move towards a neighbour, away from them or in the same direction as them. These compulsions are combined with the position and heading of the neighbours to provide a new heading for the boid.

The Couzin model shares much with Aoki’s model. It retains the three zones and their effect on the heading of the fish. However like Reynolds’ model fish outside of the range of perception have no effect at all. In addition, in a single time step, only one of the zones ever has an influence on the behaviour of the fish. The zone of repulsion (ZOR) takes precedence over the other two compulsions. If a neighbour is found in this zone then the other two are ignored and the fish will just try and swim away from neighbours in the ZOR. If no fish are found in the ZOR then only the fish in the zone of orientation (ZOO) are considered in the update of the heading. Modelfish in the zone of attraction (ZOA) are only considered if the ZOR and ZOO are empty. We note here the similarity of this configuration with Brooks’ subsumption architecture (Brooks, 1999).

The above swarming systems seem very different but they have the same foundations: they are built on simple rules, and the complex behaviour they exhibit is a by product of these, not explicitly stated by them; they involve extensive interaction between individual members of the swarm using observed information about the other individuals; and the behaviour is highly dependent on the parameters used.

Genetic algorithms (GAs) use emulations of evolution in order to solve computational problems which may be difficult to solve using more conventional techniques Goldberg (1989). The main components are a genome which specifies how the individual is represented in the algorithm, a phenotype which is how the genotype maps onto real world attributes, a fitness function which states how good each individual is and functions to perform mutation and crossover

to produce offspring. Crossover focuses the search on good values by taking two parents and recombining their genomes to create a child; mutation adds a random element to the children which increases variety in the population.

Some work has been done to use genetic algorithms to modify the behaviour of swarms. Conley (2005) used a genetic algorithm to tune a particle swarm optimisation (PSO) search. Geoboids (Macgill and Openshaw, 1998) was the basis of this work, where the swarm moves over a landscape looking for clusters of points, returning the locations of all the clusters it thinks it has found. Conley used a hierarchical fitness function and tournament selection to avoid having to assign each individual an absolute fitness value. Instead, two individuals are compared using a series of criteria, if one wins out on a test then the function stops otherwise the next test is carried out. The tests compare: the number of clusters found; the ratio of distinct clusters to total clusters; the number of dead boids (those which are in empty regions of the dataset when the algorithm finishes); the number of comparisons made (adjusted for the size of the flock) and finally the amount of the dataset searched.

Kwong and Jacob (2003) used genetic algorithms to change many parameters used by a swarm in order to induce “desirable behaviour”, that is swarms which moved in a certain way. They had no automatic fitness function to guide the GA and instead assigned a fitness to each swarm created by the GA by eye, based upon observing its behaviour as it ran. This type of fitness measure could easily be adapted for our work, but it is prone to human error when the differences between individuals are subtle (although some research has been done on methods to improve this (Khemka et al., 2009)).

(Stoops et al., 2010) examined the rules that swarms adhere to by using data mining and rule classification algorithms. A basic experiment into this issue involved running a swarm simulation based on Reynolds’ boids and recording data related to the individual’s movement (the time, position, heading, speed and separation and detection radii). A rule classifier was run on this data to create a series of potential rules. These were then tested by running the boids again but with these rules instead of the defaults. This run was compared to the original and used to modify the rules.

## Methodology

The experiments we report here used a two-dimensional version of the Couzin model (Couzin et al., 2002; Wood and Ackland, 2007) of shoaling behaviour as the basis of simulated fish movement. Like many of the other proposed models it establishes zones of perception around each fish (see figure 1). The location of neighbours within these zones governs the fish’s future movement (being attracted to neighbours in the ZOA, oriented with neighbours in the ZOO, and repelled by those in the ZOR). Our experiments were designed to determine whether it was possible to learn the pa-

parameters of a swarm of modelfish running a known model by adding an agent (robofish) to it and monitoring its behaviour relative to the modelfish. As the robofish behaviour is specified via the same underlying model as the swarm, it follows that if the correct parameters for the robofish model can be set appropriately then its behaviour should be indistinguishable from that of the modelfish. The parameters used by each robofish were encoded in the chromosome of a genetic algorithm. The GA requires a fitness function to evaluate the robofish after a run, which will summarise the robofish's interaction with the modelfish into a single numerical value. The aim of the fitness function is to accurately represent how similar the behaviour of the robofish is to the modelfish. We hypothesised that this should allow the GA to converge on the parameters used by the modelfish, under the central assumption in this work that similar parameters alone will allow a robofish to exhibit behaviour identical to a modelfish.

The motivation for the design of our fitness function was to determine if the robofish was interacting with the modelfish or travelling the arena independently. Accordingly, the experiments used the average Euclidean distance from the robofish to each of the modelfish as the fitness function. This strategy is based on two assumptions: (1), that similar, but not identical behaviour will allow the robofish to interact with the swarm (smooth fitness landscape); (2) that only one configuration of the swarm model will induce this behaviour (no local optima). It is clear that the fitness function needs to be appropriate to the learning task at hand – the parameters of the model are assumed to be impossible to estimate directly, so we can only use the emergent behaviour of the modelfish swarm as the basis for our fitness function. Since this is such an important issue, we took steps to evaluate the fitness measure with respect to the model parameters in the GA.

## Experiments

A single robofish was used in each simulation to ensure that the robofish's behaviour was determined only by its internal model and interaction with the modelfish. If more were used there would be potential for the robofish to interact each other and produce behaviour that was not programmed into the modelfish. In these experiments the only parameters to be changed are the sizes of the three zone widths ZOA, ZOR and ZOO. These were chosen as they control the main aspects of the fish's behaviour.

The parameters used by the model fish in the swarm was set throughout the experiments with parameters used in Wood's original experiment (Wood and Ackland, 2007) (see table 1). This seemed to give an aesthetically realistic swarm whose behaviour often transitioned between different types (Kwong and Jacob, 2003). This would prevent the evolution of robofish who could only swim like the others in certain swarm configurations. With the robofish sharing the same model as the modelfish, the chance of this happening

Parameter	Value
ZOR	1
ZOO	12
ZOA	13
Velocity	2.25
Blind spot	90°
World size	240
Number of modelfish	99
Number of robofish	1
Warmup time	5000
Sample time	5000
Samples	100
Mutation rate	5%
Crossover rate	90%

Table 1: Default values used throughout the experiments

is small. Not much can be done about this before the experiments are run as the behaviour created by adding a robofish to the swarm was unknown *a priori*.

A problem with using these parameters is the repulsion radius ZOR=1. Since setting it to 0 effectively removes this type of perception for the robofish, it is only possible to test what happens when the robofish's ZOR is either larger than the modelfish's or absent (the radius is an integer value). This does place a limitation on the conclusions that can be drawn from the experiments but to change these values would require additional experimentation to find other configurations which produce similar behaviour in the swarm.

The arena dimensions were also the same size as in Wood's experiment: a square 240x240. This means that each modelfish can perceive around 3.7% of the world. For all the experiments in this section the number of fish in each trial (inclusive of the robofish) was set to 100. Preliminary experiments indicated that smaller numbers of fish had a tendency to form multiple groups which either never coalesce into a single swarm or do so only after a very long time interval. It also appears that it is easier for modelfish in a small swarm to escape a group altogether and swim by themselves.

To avoid any bias in the initialisation process, the swarm was run for 5000 time steps before 5000 time steps of monitored behaviour. Here the state of the system was sampled every 50 time steps. This regime reflects the dynamic nature of swarms and reduces the risk of rare, unrepresentative states distorting the fitness estimation. A robofish has to perform well for the entire run to obtain a good fitness score. A robofish which "loses" the swarm or keeps its distance at times will score poorly. In addition, each configuration was performed 5 times to further reduce the effect of the variability in runs on the analysis. This means that each robofish configuration was sampled a total of 500 times.

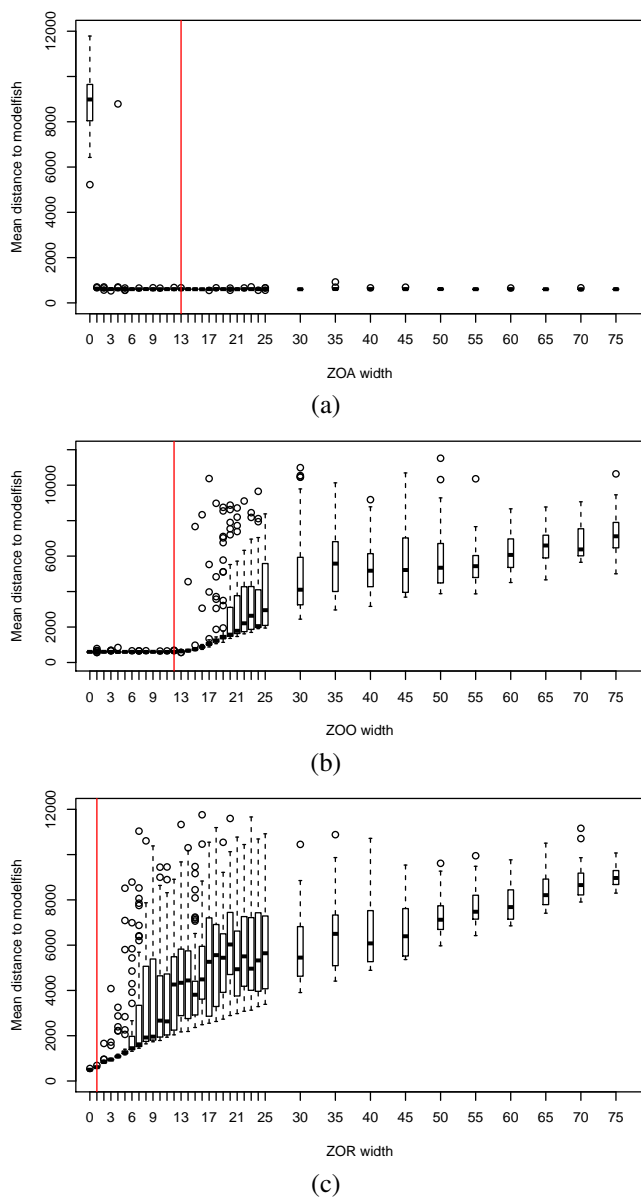

Figure 2: Effect on fitness of changes in widths of (a) Zone of Attraction, (b) Zone of Orientation, and (c) Zone of Repulsion for the robofish. The vertical red line on each plot indicates the target width value used by the modelfish.

### Fitness of zone widths

Our first experiment explored the effect of changing the value of individual zone widths on the fitness of the robofish. The position of the zones relative to the fish are interdependent, as shown in figure 1. Changing one of the widths whilst keeping the other two fixed gives us a clearer understanding of the contribution of the zone width to the emergent shoal dynamics.

Each of the three zone widths were changed from zero

Figure 3: Robofish movement (a) at time  $t$  with a ZOO, (b) at time  $t$  without a ZOO, and (c) at time  $t+1$  without a ZOO. In both cases, the robofish maintains contact with the swarm.

(eliminating the behaviour completely) to 25 (roughly double the modelfish values for ZOO and ZOA) in intervals of 1 to examine how the fitness varies around the values for the parameters actually used by the other fish. The tests were then extended using values from 30 to 75 (roughly six times the modelfish value) in intervals of 5 to explore more dissimilar configurations. Each configuration was tested over 50 trials to allow an accurate representation of the fitness of that value. Figure 2 shows the results of these experiments.

**Zone of Attraction** From figure 2(a) it appears that varying the ZOA has very little effect on the fitness of the robofish. However, when there is no ZOA (i.e. the width = 0), the average distance to the swarm is high, with large variance. The lack of any compulsion to swim towards other fish leads to the robofish being lost from the modelfish swarm. If the ZOA is present, no matter what the size, the robofish performs very well with a low average distance to the modelfish. It would be expected that a high ZOA would allow the robofish to find the swarm more easily if it became separated from the group, but the plot indicates that even a small ZOA with a width of 1 is effective in maintaining the robofish's contact with the swarm. This suggests that the ZOA has a role in limiting the chance of *escape* from the swarm, rather than directing behaviour to *seek* the swarm when swimming alone. Where a ZOA is present in a trial, the swarm has usually formed and contains the robofish by the time fitness measurements commence.

Fish in our model move at 2.25 units per time step. A fish on the margins of the swarm might only have contact with the swarm at the very perimeter of its zone of orientation. There is a small chance that this contact would be lost, and the fish might then escape the swarm if there was no zone of attraction at all. However a very small ZOA would be sufficient to induce the fish to move back towards the swarm should this occur, since those fish which were in the ZOO of the fish in the previous time-step will either still be in the ZOO or have moved to the ZOA – it is very unlikely that they will be completely out of range.

Note also that our fitness measure only samples the position of the robofish after a period of 5000 time steps. If we began to measure fitness from the initialisation period, we

Figure 4: Effects of an individual's large ZOO on shoaling interactions. Stage 1 - The robofish is at the head of the shoal. Stage 2 - The large ZOO allows the Robofish to pull ahead. Stage 3 - The swarm is entirely in the Robofish's ZOA but the robofish cannot be seen by the swarm. Stage 4 - The robofish swims back towards the shoal. Stage 5 - The robofish has rejoined the shoal

may see the effects of varying the ZOA during the process of swarm formation.

**Zone of Orientation** As shown in figure 2(b), the ZOO has a much clearer effect on the fitness of the robofish. At low values for ZOO the robofish performs very well. It is possible that the interplay between ZOA and ZOO (described above) is the reason for this. The behaviour is illustrated in figure 3, where the arrow indicates the movement vector for the robofish in the next time step. In the model at time step  $t + 1$  the ZOA allows the fish to move towards its neighbours, ZOO in the same direction of them. If ZOO is disabled the ZOA will still move towards where the neighbours are which is the same as moving in the direction they were facing at time  $t$ . As the time steps in the simulation are very small and the velocities of the fish small compared to their range of perception (a fish can move a maximum of 2.25 units per time step whereas its radius of perception (ZOA + ZOO + ZOR) is 26 units) the difference between moving towards the heading of the neighbours at time  $t$  and  $t + 1$  is very small resulting in almost identical behaviour.

The mean distance between the robofish and the model fish increases when the robofish ZOO width rises above the ZOO width of the model fish. Between 14 and 19 a slow phase change occurs from a fairly uniform fitness to a more variable, but generally less fit behaviour afterwards. We suggest that this phase change is a by-product of the behaviour a larger ZOO induces. We hypothesise the following behaviour pattern, illustrated in figure 4. The fish in the swarm constantly change relative position in the swarm as they move, due to the stochastic element of the Couzin model. Each fish therefore spends some of the time at the front of the swarm. When the robofish is at the front of the swarm, a situation arises in which the modelfish are in the ZOO of the robofish. At the same time, the robofish is in the ZOA of some of the modelfish, but since other modelfish are in the ZOO of these modelfish, the position of the robofish is ignored by the shoal (stages 1-3 of figure 4). The robofish then changes behaviour, and swims toward the swarm (stages 4-5 of figure 4). As the width of the ZOO increases, there is

an increasing likelihood that the robofish will not successfully rejoin the swarm, since it will be further away from the swarm, and the swarm is more likely to have changed direction.

An increase in the robofish's ZOO increases the distance away from the swarm that it can travel before heading back and allows the robofish to lead again at a point further from the swarm (at lower ZOO values it will rejoin instead). Both these tendencies cause the average distance from the other fish to increase as shown on the graph in figure 2(b). However this does not directly explain the increased variation seen as the ZOO increases. The variation is due to the robofish losing the swarm. The conditions for this seem to be when the robofish has left the sight of the swarm but both the swarm and robofish are moving in almost the same direction. A small deviation from these parallel headings can place members of the swarm within the robofish's ZOA in a single time step, resulting in a situation where the robofish follows the swarm but does not influence it. As the ZOO of the robofish increases, the chance of this happening increases, and small changes in direction cause the robofish to lose sight of the swarm more often. We also postulate an increase in the ability of the robofish to find the swarm again (due to the increased area of the world the robofish can now see). Overall then, as the chances of losing the swarm increase so does the chance of the robofish finding it again, resulting in a lower jump in penalty for losing the swarm. The highest numbers tested show the range of scores decrease again whilst the mean climbs further. At this point the robofish constantly loses the swarm, resulting in uniform but unfit behaviour.

**Zone of Repulsion** As shown in figure 2(c), the ZOR width seems to have a much stronger and simpler effect on fitness than the other two variables. Simply put, the larger the ZOR the further away the robofish is from the others in the swarm. Although the upwards trend is visible from the start, a phase transition of the kind seen with ZOO is shown from around 3 to 7. Once again this is where the robofish starts to lose the swarm on an increasing number

Figure 5: Distribution of fitness at end of 50 generations of 20 trials of the GA. Column 'M' indicates the distribution of fitness for the modelfish

of runs, showing increasing variance in the mean distance to the shoal fish.

### Evolving the model parameters

The previous section demonstrated a relationship between changes in the individual model widths and mean distance to the shoal fish. In this section, we show how a genetic algorithm can be used to find combinations of widths for the ZOA, ZOO and ZOR that minimises the mean distance to the swarm.

We maintained a population of 20 robofish models per generation throughout the trial. This was a compromise between having a large population size (which could explore a sizable portion of the solution space) and minimising the computation time. This is important as each genome must be tested independently since we can only have one robofish evaluation per swarm, meaning that the genetic algorithm will run very slowly. Each robofish configuration was evaluated 5 times.

It was not our intention to evaluate a new configuration of a genetic algorithm. Accordingly, we implemented our genetic algorithm using PyEvolve (Butterfield et al., 2004). Crossover was set to 90%, and mutation (occurring with a 5% chance) changed the Zone widths following a Gaussian distribution with variance of 5% of the current value. The genetic algorithm was run for 50 generations. This was repeated 20 times to estimate the consistency of convergence.

The robofish's genome consisted of the widths of the three zones which were to be modified; the ZOA, ZOO and ZOR. These were stored as integers.

The three zone widths were initialised with random integers in the range [0,75]. The Pyevolve default tournament selection method was chosen to select fit individuals for subsequent generations.

Figure 5 shows the final distribution of mean distance to swarm fish for the robofish population in the final generation of the 20 runs of the genetic algorithm. The mean distance to shoal fish for robofish with the same width values as the

model fish is shown in the column marked 'M'. It can be seen that trials 3, 5, 6, 10, 14 and 18 have not fully converged, but the other fourteen trials show that the genetic algorithm has successfully reduced the mean distance to the swarm fish, as specified by the fitness function. Those trials which did not converge were composed of a mixture of individual models with a combination of low and high mean distances to the modelfish, indicating that it is likely that the runs would eventually converge to low average mean distances across the population if allowed to run for longer.

Note that the mean distance to shoal fish was higher in the control robofish 'M' that used the model zone widths. This reveals an issue with the fitness function - it was designed to evolve a fish that interacted with the shoal, but there is nothing in the fitness function to induce the evolved robofish to *mimic* the behaviour of the model fish. This is why the mean distance is reduced to a minimum, rather than converging on the value that the modelfish parameters generate.

To further illustrate the effect of the fitness function, figure 6 illustrates the change of fitness of the robofish configurations for trial 19, along with corresponding distributions of the three zone widths. In this trial, the genetic algorithm is effective at reducing the mean distance to the swarm. The target widths for the ZOA, ZOO and ZOR are shown as a red line on the bottom three figures.

The width of the ZOA shows the biggest difference between the evolved value and the model value. This is not surprising for two reasons. Firstly, as shown in figure 2(a), the ZOA has little effect on the mean distance to shoal, so it is free to vary. What might explain the drift of ZOA width to such a large value? We assert that a large ZOA is useful in allowing the robofish to find the swarm reliably. If the robofish has not found the swarm by  $t = 5,000$ , then its chance of being selected for the next generation will be reduced.

Both the ZOO and ZOR widths are much more similar to the model values. We claim that the value of the model ZOO is learned effectively by the GA. The ZOR tends to converge to a value of zero, compared with the model value of one. This is a small error, but the consistency of the error leads us to conclude that this value allows the robofish to have a lower mean distance to the modelfish than the modelfish have to each other.

Finally, we note that the ZOO+ZOR widths for the evolved robofish are almost identical to those for the modelfish. This implies that the outer radius of the ZOO, as specified by ZOO+ZOR is a critical parameter in determining the mean distance to other fish.

### Conclusions

The work presented here has started to explore the ability of genetic algorithms to extract important parameters related to a swarm's behaviour. It is only the start of what is possible in this field. Many more aspects can be explored in relation

Figure 6: Run 19 of the GA. Plots from top to bottom: Fitness; Convergence to ZOA; Convergence to ZOO; Convergence to ZOR

to the goal of estimating swarm behaviour models via the interaction of configurable agents with swarm agents.

It is well known that the interactions between the zones of behaviour in the Couzin shoaling model lead to an emergent swarm. In this paper, we have investigated ways of recovering the underlying model parameters of the swarm indirectly, via the interactions of an individual with the swarm. The long-term goal of this work is to fit models to observations of shoaling of wild animals. Our initial trials, varying only one of the zone widths whilst holding the others constant, revealed the following observations:

- A ZOA is needed to produce a swarm (i.e. the ZOA width must be greater than zero), but the size of the ZOA makes no difference once the swarm is formed.
- The larger the ZOO the wider the swarm distribution, since individuals can influence the direction of the swarm whilst remaining relatively widely dispersed.
- The ZOR is not necessary for a swarm to evolve. It merely controls the minimum distance between model fish. However, in physically embodied experiments (using robots or fish), it is clear that a ZOR is necessary to reduce the chance of collisions.

The average Euclidean distance to the modelfish was used as the fitness function, which proved effective in evolving individuals which were similar to the modelfish in their behaviour, and had similar values for ZOO and ZOR. The main reason for the difference in these parameters was the simplicity of the fitness measure, which only used the distances between the robofish and the modelfish and made no reference to the distance of modelfish to *each other*. If this technique were to be used with real fish, it would be possible to do this using computer vision techniques, although issues with sampling time might arise.

We suggest that if the measure was changed to use the distance the modelfish are from each other as the target distance rather than simply trying to minimise the mean distance to modelfish, then a more accurate estimation of ZOO and ZOR could be expected. This formulation would penalise robofish that swim too closely to the modelfish as well as those which swim too far away from them. In addition, the ZOA was not well estimated in the framework we devised, but we suggest that this too could be addressed by basing a fitness measure that included the period of shoal formation, rather than basing fitness solely on measures of the swarm after it has formed. Other measures such as the spatial point process measure  $C$  (Getis and Boots, 1978), which compares an individual's distance to its nearest neighbours against a set of randomly determined points in the world space, could also prove to be effective in developing a fitness function that could recover the model parameters.

In addition to a more sophisticated fitness function, other work could focus on exploring the model more fully. The

results gathered from these experiments could vary greatly depending upon the number of robofish used, the time at which the robofish are introduced (whether a swarm has already formed at that point) or the total size of the swarm. These variables would change the interactions between fish and robofish in different ways, potentially producing wildly divergent emergent effects. The results obtained by these experiments would allow swarming behaviour to be understood more fully, potentially providing valuable insights into the way swarm models are designed and configured.

Another clear area of further work is to look into whether this process can be applied to different models of swarming behaviour. There is little reason to suspect it would fail with the similar models from Aoki and Reynolds (although if this were the case it would raise interesting questions about the nature of these models and the extent of their differences), but adapting it to work on more varied models such as ants, termite mounds or wasp nests may prove more challenging and explore the process of extracting parameters more fully (as well as exploring the individual models being tested).

Of course if these methods are ever used on real life swarms it is unlikely that they will correspond exactly to the models proposed so far. By incorporating the ability for the algorithm to modify the model itself (rather than just the parameters of the model), the process could become far more robust at finding an accurate model of behaviour. This could be done by either switching from a genetic algorithm to genetic programming or by changing to genome representation which allows the model to be altered (such as changing the meaning of zones and limiting the number of neighbours looked amongst others). The increase in flexibility this would produce would allow the process to be applied to far more problems, perhaps allowing novel swarm models to emerge via genetic processes.

## Acknowledgments

The authors thank A. Jamie Wood for provision of source code that formed the basis of these experiments. Simon Hickinbotham is funded by the Plazzmid project, EPSRC grant EP/F031033/1.

## Abstract

Division of labour, or specialization, is common in many types of insect colonies. It emerges in some of these societies as a result of age polyethism, whereby the division of labour is tied to the age of the individuals. One known method that explains this is social inhibition. Individuals release pheromones when they interact with other agents. The strength of their pheromones is tied to their age. These pheromones inhibit the desire of other agents to perform the same task. Using social inhibition, individual agents can be allocated among the available tasks to be performed related to the colony. We apply a variation of this approach to the problem domain where agents can divide their time among multiple tasks. While age is not a factor, agents differ in their skill at performing each task. We create a weight-allocated social inhibition approach whereby more skilled agents inhibit the desire of less skilled agents to perform a task. We are able to see that this approach drives agents toward tasks where they have comparative advantages. This leads to an increase in the division of labour within the population. While inspired by social insects, this approach is easily applicable to agents in other domains.

## Introduction

Specialization is where individuals produce goods and services beyond local or personal need, depending upon other individuals to supply other needed goods. There are many varying definitions of specialization, with most taken from the archaeological, biological and economic fields. One definition from archaeology is that specialization is “the production of substantial quantities of goods and services well beyond local or personal need, and whose production is generally organized, standardized and carried out by persons freed in part from subsistence pursuits” (Arnold and Munns, 1994). By choosing to specialize, specialists must obtain some or all of their subsistence goods through exchange with others (Evans, 1978). There are varying levels of specialization, ranging from being able to sustain oneself, while simultaneously producing goods for the consumption of others, to complete dependency upon exchange with others for subsistence goods. Dependence upon others for subsistence was viewed by Childe as the essence of economic specialization (Childe, 1951).

Specialization allows individuals to maximize their productivity by exploiting their environment (Murciano, 1997), and occurs because entities belong to a community of mutual interest, cooperating to serve that mutual self-interest (Spencer et al., 1998). Specialization may be assigned, as in caste systems, or chosen by an individual driven by varying means, including genetic, social and economic. Another term for specialization is division of labour, which is defined by Hollbloder as “...when individuals can be turned into specialized working machines, an intricate division of labour can be achieved and a complicated social organization becomes attainable even with relatively simple repertory of individual behaviour” (Hölldobler and Wilson, 1990).

There are both internal and external factors that influence an individual’s choice of specialization (Beshers and Fewell, 2001). Internal factors include genetic, neural, hormonal and experience elements. External factors include economic factors such as demand (stimulus) and social influences (Julian, 1999; O’Donnell, 1996; Robinson et al., 1989). It seems that no single behavioural model may fully explain division of labour in complex systems (Traniello and Rosen-gaus, 1997). Different models and approaches have different assumptions, which makes it particularly difficult to compare the effects of factors across different approaches.

The study of specialization is important to several fields. For instance, archaeologists study specialization to understand the changes in societies as a result of the emergence of specialization. It also gives insight into why individuals would choose to produce certain goods over others. From the biological perspective, specialization helps to explain the behaviour of biological creatures such as ants, wasps and bees (Larsen, 2001; Page et al., 1998; O’Donnell, 1996), which have been empirically shown to specialize based on tasks. Economically, specialization is studied to understand its effect upon a society’s economy. It further serves to study how a market may grow or contract based on the specializations present, as these specializations lead to increases in the productivity of market systems (Murciano, 1997). Allyn Abbot Young points out that a productive individual increases the supply of certain commodities, while simultane-

ously increasing the demand for others (Young, 1928). In spite of its role in economics and biology, little is known of the origins and causes of specialization and exchange (Beaudreau, 2003).

In this paper we focus on the social approaches to artificial agent specialization. Here we define an agent as an autonomous social party that can perform several tasks with varying levels of skill. Being social, these parties can also be influenced by their peers across their social networks. It is our hypothesis that competition will drive agents to allocate more of their resources to produce goods with which they possess a comparative advantage in relation to their competitors. As the primary differentiator of efficiency in our model is skill, it can be assumed that more skilled agents will have a comparative advantage over their less skilled competition. In this individual based model, these self-interested agents will be influenced towards performing tasks that will maximize their own productivity. We believe this approach will lead to significant increases in the overall level of specialization within an agent population. In the next section we introduce the social inhibition model from which this work is primarily inspired. We then describe our generic model that uses weight-based allocations. Finally, an experimental setup is presented and discussed with concluding remarks.

### **Social Inhibition**

There are several social models for the emergence of agent specialization. One such method is social inhibition, which implies that as agents choose their specialization, they notify other agents that they have done so, reducing their desire to also choose this specialization. To put that idea in economic terms would be that choosing a specialization reduces the demand (stimulus) for that specialization. Social inhibition aims to explain concepts such as temporal polyethism, which is division of labour based on age, as a result of the interaction between behavioural development and the inhibitory effects of other workers (Huang and Robinson, 1992; Naug and Gadagkar, 1999; Beshers and Fewell, 2001). Temporal polyethism can also be explained experientially, as older agents would have more experience, and thus more knowledge upon which to base their actions (Ravary et al., 2007). This model is more concerned with the physiology of workers and their interactions. Initially, the model took the form of an activator-inhibitor approach, whereby all agents would eventually mature to perform specific tasks, but inhibitors from current performers of these tasks would slow their activation.

Naug and Gadagkar presented a social inhibition model that aimed to explain the age polyethism in wasp species (Naug and Gadagkar, 1999). Their model was in turn based on the verbal model of Huang and Robinson (Huang and Robinson, 1992). In Naug and Gadagkar's model, each agent has two pods: one that increases its own preference for a task, and another that inhibits the preferences of agents

it interacts with for the same task. Their model claimed that individual specialization is emergent from the increase in activator due to age, as well as the amount of inhibitors exchanged when agents interact. The model assumes that all agents possess the same preference and skill level for task performance, which makes it difficult to adapt to situations such as those we aim to address.

The effect of competition on task specialization was examined in (Merkle and Middendorf, 2004). Competition was shown to lead to the occurrence of specialists as an emergent phenomenon dependent on the size of colonies. Their model was based on a genetic preference model though, whereas our model is based on social interactions. They also studied differing demands for tasks, something which we do not explore here.

Another social interaction model was explored in (Gordon and Trainor, 1992). Agents had an active and inactive state for the four tasks in the model. The agents communicate with each other, giving them some idea of how many other agents are performing the same task. These interactions between agents is designed such that the system will trend toward a stable set-point where there is a balance of active and inactive agents for each task. Like the above mentioned models, they also assume that agents do not possess an innate preference or skill for tasks.

A non-social model that is also relevant is (Lavezzi, 2003). Lavezzi's model shows that the amount of specialization and level of per capita output depends on competition, agent connectivity, agent thresholds, and initial conditions such as number of agents and their connectivity. An agent's potential to choose a specialization is limited by the amount of other agents performing the same task, as well as the stimulus level for that task. Agents of course have to know about the level of competition, or be directly aware of the changing stimulus levels. In either of these two situations, agents are required to have excess knowledge of their economic environment. While non-social, we have found that a lot of the effects claimed by Lavezzi are also evident in our model.

The existing social models have several other shortcomings, several of which we look to address. In these models, agents are only able to perform one task per unit of time. In our model, we aim to deal with situations where agents can divide their time among several tasks. Take for example something like human agents, such as those found in (Kohler et al., 2007), who have several tasks to perform in each year such as farming, hunting, getting water and getting wood.

In the social inhibition model, which is aimed at age based specialization, the social influence of other agents do not directly determine the specializations that others will choose. Tasks must first be ranked in a way related to age, then agents are ranked by fit for those tasks. After that, agents are then assigned based on the number of workers needed for that task. We think that while this may be appropriate in insect colonies, it makes the model difficult to adjust to

agent populations where tasks may not have priorities. In our model, we assume no priority among tasks.

## Approach

Our approach is not aimed at system optimization, whereby the system itself tries to be the most productive possible. Instead, agents should be able to emerge the specializations that they are most suited for in their given environment. We assume the existence of a set of tasks  $T$ . Each element  $t$  in  $T$  is a task that can be performed by an agent. Each agent has a level of skill associated with each task. The skill level may be static, or it may be determined by the agent's previous success at performing the task. This allows for skill levels that may correspond with fitness functions in evolutionary algorithms. This skill level is quantifiable, comparable and monotonic, such that  $sk_a(t) > sk_b(t)$  means that agent  $a$  is more skilled than agent  $b$  at performing task  $t$ . All agents assume they can perform the task perfectly. The level of skill is then reflected in the amount of inhibition that agent then releases when they interact with others. Agents are thus able to determine their true relative skill level through interactions with other agents. The strength of inhibition, which we refer to as the influence rate, depends on each agent.

In our test simulations, we assume that all agents have the same level of influence. This is not required, and it is quite possible for different levels to make sense in a domain. For instance, we can create the effect of age polyethism if we were to have the influence rate grow with age. In that case, to create task prioritization, we can have the level of influence vary by task as well. In addition to skill, agents have to divide their time among tasks. They therefore need to track their allocations, which they do internally. Note that while we refer to time, that is simply one idea of a resource. This model does not require the resource to be time, but it can be money, food, or any other divisible resource. The simulation is composed of a set of interacting agents within a social network that can all perform the same tasks at varying skill levels.

## Problem Description

Given agent  $Ag$ , the set of tasks available to  $Ag$   $T_{Ag}$  and a resource  $R_{Ag}$ , how does an agent allocate its  $R_{Ag}$  among each task  $t$  in  $T_{Ag}$ ? So,  $\sum x_i = S(R_{Ag})$ , where  $i$  is each task in  $T_{Ag}$ ,  $S(R_{Ag})$  refers to the amount of the resource  $R_{Ag}$  available, and  $x_i$  refers to a fraction of  $S(R_{Ag})$ . The problem also involves the following conditions: The problem is continuous over a period of iterations,  $S(R_{Ag})$  changes between iterations and  $x_i$  is allowed to change over iterations.

## Weight-based model for resource allocation among tasks

For each agent  $Ag$ , we propose a set  $ALLOC$ , where  $e_i \in ALLOC \Rightarrow$  there is a task  $i$  in  $T_{Ag}$  and  $e_i$  represents the

weight allocated to task  $i$ . Task weights in  $ALLOC$  are relative, therefore for a given task  $i$  and a resource to be allocated  $R_{Ag}$ , the amount of  $R_{Ag}$  to be allocated to task  $i$  is:  $\frac{e_i}{S(ALLOC)} \times S(R_{Ag})$ , where  $S(ALLOC)$  is the sum of all elements in  $ALLOC$ . We make no assumptions about the initialization of the weights in  $ALLOC$ ; they can be randomly assigned, or initialized by some other method. A task having a weight of 0 will result in the task being allocated none of  $R_{Ag}$ . For simplicity, we will assume  $R$  refers to time for the rest of this paper. We also normalize the weights in  $ALLOC$  such that  $S(ALLOC)$  is always equal to 1.

## Model outline

Agents influence other agents when they interact. In some networks, such as kin network, it can be assumed that they interact with all their neighbours in each time step. The amount of influence is dependent on skill level. The higher the skill level, the higher the level of influence. When an agent interacts with another, it positively reinforces its own behaviour, while also inhibiting the other agent. The amount of self-reinforcement is the same amount that it inhibits the other agents. After all agents have interacted, the agent subtracts the level of inhibition it has received from the level of activation it has provided itself. The agent also self-activates itself, such that an agent that does not interact with any other agents will still change its behaviour. These effects result in the change of the allocation levels for the agent.

## Agent Properties

### Agent Attributes

Each agent has the following attributes:

- An allocation set  $ALLOC = \{ t_i \leftarrow [0,1] \}$ , for all tasks  $i \in T$ , where  $t_i$  is the fraction of time the agent will spend on task  $i$ .
- A skill set  $SKILL = \{ s_i \leftarrow [0,1] \}$ , for all tasks  $i \in T$ , where  $s_i$  is the skill of the agent at performing the task  $i$ . If an agent cannot perform a task  $p$ , then the value of  $s_p$  would be 0. The skill level for a task may be dynamic and updated regularly. The skill value as a function must be monotonic though, such that if agent  $Ag1$  has  $s_i$  0.5 and agent  $Ag2$  has  $s_i$  0.7, then we can say that  $Ag2$  is better than  $Ag1$  at performing task  $i$ .
- A set  $PODS = \{ p_i \}$ , for all tasks  $i \in T$ , where  $p_i$  is a 3-tuple  $(A, SA, I)$ . In this 3-tuple for task  $i$ ,  $A$  represents the activator store for the agent,  $SA$  is the level of self-activation, and  $I$  is the inhibitor store for the agent. The agent will increase the weight of the associated task when  $A+SA > 0$ , and decrease it when  $A+SA < 0$ .

The idea behind self-activation is the inclination of an agent to perform more of the task at which they are best. This value should be large enough that it will allow an isolated

agent to specialize over a long period of time, but it should also be small enough that it doesn't overwhelm the social pressure created by stronger competitors.

### Agent Inhibition

The level of inhibition  $I$  in an agent's pod for a task  $i$  is determined by several factors:

- The skill level of the agent at performing task  $i$ .
- The size of the agent's social neighbourhood.
- The influence rate,  $IR = (0, 1]$ , which is a parameter that determines the strength of an agent's influence. This parameter can be universal, or variable for each agent. It is also possible that the influence rate can be different for each task. We can re-create the effect of polyethism if we were to make  $IR$  dependent upon the age of an agent.

### Agent interaction

When agents  $Ag1$  and  $Ag2$  interact, for each task  $t \in T$ , we obtain the values in  $Ag1$ 's pod  $pt$  for task  $t$ , and  $Ag2$ 's pod  $pt$  for task  $t$ . The value in  $Ag1$ 's  $A$  will be decreased by  $Ag2$ 's  $I$  and vice versa. Each agent will also increase its own  $A$  by its  $I$ . This method allows agents to influence each other only when they interact.

Since agents both exchange inhibition, and inhibition level is tied to skill and influence level, the more skillful and influential agent would have a greater effect on a neighbour than a less skillful and influential competitor. While the influence of the "better" agent would be stronger, the weaker agent would still inhibit the stronger one. It is also possible for agents to be considered to interact on every iteration, in which case agents would inhibit all others in their neighbourhood. It should be noted that the level of self-activation plays no role when agents interact.

### Agent Attribute Updates

During each time period, agents will have performed their tasks based on their allocation weights (ALLOC). If the skill set is dynamic, then it would be updated based on the results of task performance. The influence rate of each agent would also need to be updated. If agents have different influence rates for each task, then the updates would need to be applied for each task.

Agents will then update their allocations based on each task pod. Given a normalized allocation  $ti$  for a task  $i$ , and a pod  $(a, s, x)$  for the same task  $i$ , then  $ti$  will be updated as:

$ti = ti + a + s$ . That means that the amount of self-activator  $s$  will be added to the activator  $a$ , and the sum of that added to the current weight. If an agent was overall more skilled at a task than the other agents it interacted with, then its activator level  $a$  should increase. If it is less skilled overall, then the level should decrease, resulting in a negative value for  $a$ . After all task weights are updated for

an agent, the values are again normalized, resulting in the sum of all weights in the agent's ALLOC being 1.

## Experiments and Results

To measure the level of specialization within a population, we use a measure developed in (Gorelick et al., 2004). The measure quantifies the degree to which agents in a population are specialized. We have each agent record their task allocation amounts. These amounts are then stored in an  $n \times m$  matrix, with  $n$  being the number of agents and  $m$  the number of tasks. We then normalize this matrix such that the sum of all cells is 1. The mutual information and Shannon entropy index (Shannon, 1948) are then calculated for the distribution of individuals across tasks. Finally, dividing the mutual information score by the Shannon entropy score will provide a value between 0 and 1. A score of 0 indicates a population with no specialization, while a score of 1 indicates a fully specialized population (Gorelick et al., 2004).

We test our method across several parameter types. These are: the type of network, the number of tasks, the number of agents, and the influence rate. We test with two network types, small-world networks and random networks. Small-world networks (Milgram, 1967) are networks whereby most nodes are connected by a small degree of separation, with the existence of a power-law structure among many nodes. Two famous examples of a small-world network are the '6-degrees of separation' phenomenon found within the US population (Milgram, 1967) and a similar phenomenon among many sites on the World-Wide Web (Bu and Towsley, 2002). With random networks, each node will just be randomly connected with another node. We use the same amount of total edges in both network types, dependent upon the number of agents.

We tested for 2, 4, 10 and 20 tasks. Most studies involve 2 to 5 possible tasks (Waibel et al., 2006), while some insect colonies have anywhere from 20 to 40 specializations (Beshers and Fewell, 2001). Although we could have tested for more possible tasks, we observed that 20 would be sufficient to demonstrate the process. As for the number of agents, we tested smaller groups of 10, 50 and 100 agents, as well as larger groups involving 500 and 1000 agents. Each agent acts after the previous step for all others, meaning that all agents operate in the same time step. Tasks are all assumed to take the same amount of time to perform. We tested with a variety of influence rates, these being 0.05, 0.1, 0.25 and 0.5. The influence rate was the same for all agents during each run. We used a constant self-activation rate of 0.05. All agents also have the same capacity for task performance, that is to say the same amount of time available to be allocated. We ran each combination of parameters 10 times.

Each agent would be created with random task allocations. Thus for each available task, the agent would assign a percentage of their time to be spent on that task. As the metric developed in (Gorelick et al., 2004) is dependent upon

these task allocations, different populations of agents would necessarily have different initial levels of specialization. As such, it is not possible to compare the initial and ending specialization levels across runs within the same network type, even with the same parameter settings. The initial populations would be the same for different network types when all other parameters are the same. Considering these conditions, we measure the change in the level of specialization over a run. In the tables given, rows represent the number of tasks and columns represent the number of agents. Tables 1 through 4 illustrate a representative sample of our overall results. They report the average division of labour (DOL) and standard deviation with influence rates (IR) of 0.05 and 0.5 for both small-world and random networks. The DOL values are average multiples (DOL at beginning of run / DOL at end of run) of the initial level of population specialization over the 10 runs for each parameter combination. Thus a value of 3.3 indicates that there was a 230% increase in the level of specialization. For brevity, the results of other influence rates are not shown.

The level of specialization increased in all 1600 runs that we simulated. In our small-world networks, the average result was a multiple 3.2 over the initial values, with a standard deviation of 0.75. With our random networks, the average result was a multiple of 3.9, with a standard deviation of 0.97. We believe that the higher increase in our random networks is due to the higher average number of connections between agents. In small-world networks, several agents have a lot of neighbours while most have only a few. As agents are influenced by interacting with others, having more interactions result in each agent moving toward its optimal state faster. This suggests that increasing the level of connectivity between agents will result in more pronounced increases in specialization.

Our results may be depressed by the emergence of equilibrium states within our populations. This is the case when adding more iterations will not result in any increase in the population's level of specialization. This emergence of equilibrium states is not surprising though as it is predicted in (Young, 1928). As the initial level of specialization is randomly between 0 and 1, it is the case that a population with a high initial level of specialization would not have much room for improvement. We would not expect to see a state of equilibrium if we had used a dynamic society, as new births, deaths, and other state changes would keep the situation in a state of flux (Lavezzi, 2003).

We noticed that in many cases agents would not become fully specialized. This may be in spite of the fact that they may be significantly better at a particular task than all competitors. This is because they would still have some pressure to perform other secondary tasks where they may still have some advantage. This became more pronounced as the number of tasks increase. In such cases, agents may possess comparative advantages in multiple tasks, and thus the moti-

vation to increase their allocation in both. As the allocation system is weighted, the increases in both weights offset each other.

While we did notice that in most cases increasing the level of influence would also result in a higher level of specialization, this does not occur in all cases. In our simulations, the level of specialization would decline in many cases when going from an influence rate of 0.25 to one of 0.5. Because of the different initial populations and specialization levels, we are unable to study the effect of changing agent and task amounts.

## Conclusion and future work

In this paper we presented a new social inhibition model for the emergence of specialization in agent societies. We showed that this model is able to significantly increase the level of specialization in a random population. While several current models deal with domains where agents can only perform one task at a time, our model deals with having agents that have to allocate their time among several tasks. We have shown that when agents are differentiated by skill level, competition and social inhibition can be used to increase division of labour. We found that our agents will increase their allocation of time among tasks for which they possess a comparative advantage over their neighbours. This follows a well established law of economics. Surprisingly, we also found that using our weight based approach, agents will not necessarily specialize on the task they are most efficient at. This is because the change in allocations for multiple tasks may offset each other. The result seems supported by real world experience, where we have yet to see a modern nation completely specialize on one product. Our model is created in a way that makes it applicable to many domains.

We intentionally kept several parameters abstract because we would like to keep the approach general. Many of the parameters used can be changed to accomodate different domains. We also didn't state how it is that agents interact for the same reason. Interaction could be either broadcast, exchanged through the environment, or exchanged through message passing. The meaning of the social network and its connections is also left open intentionally, such that it could represent a wide range of topics, such as a topographical neighbourhood, or even a collaboration network.

We currently do not account for different levels of resource availability. We would like to investigate what changes if any the model would need to work under those conditions. In addition, we assume that demand is always equal to the amount of a resource produced. It would be a good idea to investigate different levels of demand either globally or locally for each task. We would also like to see how the model performs under dynamic environmental conditions. We would like to apply the model in concrete domains such as human society simulations, or even social insect simulations. We believe that this model can encompass

## Abstract

In the framework of *Agent-Based Complex Systems* we examine dynamics that lead individuals towards spatial *segregation*. Such systems are constituted of numerous entities, among which local interactions create global patterns which cannot be easily related to the properties of the constituent entities. In the 70's, Thomas C. Schelling showed that an important spatial segregation phenomenon may emerge at the global level, if it is based upon local preferences. Moreover, segregation may occur, even if it does not correspond to agent preferences. In real life preferences regarding segregation are influenced by individual contexts as well as social norms; in this paper we will propose a model which describes the dynamic evolution of individuals tolerance. We will introduce heterogeneity in agents' preferences and allow them to evolve over time. We will show that it is possible to dynamically get a distribution of tolerance over the agents with a low average and in the same time to deeply limit global aggregation. As the Schelling's model showed that individual *tolerance* can nevertheless induce global *aggregation*, this paper takes the opposite view showing that *intolerant* agents can avoid *segregation* in some extent.

## Introduction

In his article Schelling (1971), Thomas Schelling developed a model of segregation and analysed how a simple preference not be a part of a minority in one's neighbourhood, without necessarily favouring dominance of one's own type, can generate small micro-shocks which have drastic consequences at the macro level. Aggregation happens through a chain reaction, even though the agents do not wish such an extreme situation. Agents interact only locally with their neighbours: every one agrees to stay in a neighbourhood with individuals that have the opposite type, only if there are enough individuals with the same type in the vicinity. This proportion is fixed by a threshold, denoted by the *tolerance* ratio.

More generally, the 'micromotives and macrobehaviour' problematic asks the question of the compliance between local micro-motives and the resulting macro-behaviour. Today, as problems become more and more complex, this problematic is more relevant than ever. In the fields of sociology,

economics, ecology, energy, ..., each one has many *a priori* on the global consequence of his own actions. Most often, a person thinks in good faith that his action will produce faithful results for the community. For example, one can think that:

(a) *intolerant* behaviour lead to *high segregation*

(b) *tolerant* behaviour lead to *low segregation*

Let  $i$  (resp.  $\bar{i}$ ) stands for individual intolerance (resp. tolerance) and  $S$  for a high level of global aggregation/segregation. Hypothesis (a) and (b) can be reformulated by the *micro to macro link*  $[i \rightarrow S]$  and  $[\bar{i} \rightarrow \bar{S}]$ . The Schelling's model provides first an example for the expected case  $[i \rightarrow S]$ ; but, as it shows that tolerance can nonetheless induce a significant level of segregation, it provides also an example for the paradoxical link  $[\bar{i} \rightarrow S]$  where the macro-outcome is intuitively inconsistent with the preferences of the agents who generate it.

This paper shows that macro-segregation can be deeply limited despite the presence of intolerant agents; thus, it provides an example for the dual case  $[i \rightarrow \bar{S}]$ . In the model we propose, each agent has his own threshold of tolerance. At each time, for each agent, the tolerance is adapted using some meta-rules. As a consequence, the emergent state of the 'world' results from a spatio-temporal adaptive dynamics. The scientific question addressed in this work is an evolution of the Schelling Model, which consists in considering an adaptive micro level of tolerance and analysing its impact on the segregation phenomenon observed at the macro level.

This article is organized as follows. In section 2, we propose a generic model of satisfaction. Section 3 shows the global behaviour of models using the simple *Eulogy to Fleeing* rule. Section 4 examines the effects of introducing adaptive tolerance thresholds on the nature of frontier between patterns. Section 5 proposes the new model which allows to conciliate local intolerance and a low level of segregation. Finally, future works are listed and conclusions are drawn.

## A generic model of satisfaction

The Schelling's checkerboard model of residential segregation has become one of the most cited and studied models in many domains as economics, sociology, complex systems science,... Páncs and Vriend (2003), Zhang (2004), Gerhold et al. (2008), Banos (2009). It is also one of the predecessor of agent-based computer models Rosser (1999). Taking inspiration from this model, we define a more generic model of satisfaction (GMS).

The GMS is similar to a 2-D cellular automata model: the 'world' includes numerous agents embedded on a toroidal grid. For each agent, the perception is centered on his local neighbourhood only, where the neighbourhood is constituted of the nearest cells surrounding him. We note  $d_i(t)$  the social *degree* of the agent  $a_i$  at time  $t$ , that is the number of agents in its neighbourhood. Since some locations remain empty, the size of the neighbourhood is the maximum number of neighbours an agent can have. There are two types of agents and each agent has its own type. During a run the agent's type cannot change. The satisfaction of one agent is relative to the type of the agents in its own neighbourhood. For convenience we will denote by a color, *yellow* and *green*, the two possible types.  $Y$  (resp.  $G$ ) represents the set of agents in the *yellow* type (resp. *green* type). Thus, the number of agents is  $(\#Y + \#G)$  and at the global level, the basic hypothesis is  $(\#Y = \#G)$ . At each time  $t$ , for each agent  $a_i$ ,  $s_i(t)$  (resp.  $o_i(t)$ ) represents the number of neighbours with the *same* type (resp. *opposite* type), so  $s_i + o_i = d_i$ .

### From Thresholding to Satisfaction

For each agent  $a_i$ , we assume that there is some quantity measured by the variable  $Q_i$  in the range  $[0, 1]$  which depends on  $s_i$  and  $o_i$ . At each time  $t$ , the value *required* $Q_i(t)$  is a number in the range  $[0, 1]$  which denotes the threshold under which the agent is satisfied according to  $Q_i(t)$ . We define the local boolean indicator *satisfied* as:

$$satisfied_i(t) = (Q_i(t) \leq requiredQ_i(t)) \quad (1)$$

Finally, we define the global indicator *satisfactionRatio* in the range  $[0, 1]$  as:

$$satisfactionRatio(t) = \frac{\#\{satisfied_i(t) = true\}}{\#Y + \#G} \quad (2)$$

This is the ratio of satisfied agents at time  $t$ ; if it is equal to 1, then all the agents are satisfied at time  $t$ .

### Local rule

Once the static description of the model is specified, one must add rules that govern the dynamics of agents' movement. At each time, the motives of each agent are driven by its own satisfaction: an unsatisfied agent is motivated to

move away to one vacant location. The gap between micro-motives and macro-behaviours is due to overlapping neighbourhoods: an agent who moves according to its own interest affects not only the neighbourhood it leaves and the one it arrives in, but also affects, in the long run, all the agents. In GMS we do not fix how an agent moves; this will be specified later when the model will be instantiated. One can only say that there are many ways for an unsatisfied agent to move to a vacant place.

### An index to measure the degree of aggregation

To have some insight into the aggregation level, it is necessary to measure the global aggregate over the world. We reformulate measures proposed by Schelling, Carrington and Goffette-Nagot Schelling (1971), Carrington and Troske (1997), Goffette-Nagot et al. (2009). First, we define a global measure of *similarity* as:

$$s(t) = \frac{1}{\#Y + \#G} \sum_i (1 - Q_i(t)) \quad (3)$$

Then, we define the *aggregateIndex* by

$$aggregateIndex = \begin{cases} \frac{s - s_{rand}}{1 - s_{rand}} & \text{if } s \geq s_{rand} \\ \frac{s - s_{rand}}{s_{rand}} & \text{else} \end{cases} \quad (4)$$

where  $s_{rand}$  is the expected value of the measure  $s$  implied by a random allocation of the agents in the world. A null value for this index corresponds to an average random configuration. The maximum value of 1 corresponds to a configuration with two homogeneous patterns only.

### The Schelling's model of segregation

The Schelling's model of segregation is a particular case for the generic model of satisfaction. In the following we are going to indicate its specificities.

**How to compute satisfaction?** In the Schelling model the quantity  $Q_i(t)$  takes into account the proportion of neighbours of the opposite type; it is computed as the ratio between the number of neighbours having the opposite type and the social degree.

$$Q_i(t) = \begin{cases} \frac{o_i(t)}{d_i(t)} & \text{if } d_i(t) \neq 0 \\ 0 & \text{else} \end{cases} \quad (5)$$

For example, if a yellow agent  $a_i$  has three yellow neighbours and two green neighbours,  $Q_i = \frac{2}{5}$ . If there are no neighbours for the agent (i.e. if  $d_i = 0$ ),  $Q_i = 0$ . If all neighbours have the same type (i.e. if  $o_i = 0$  and  $s_i \neq 0$ ),  $Q_i = 0$ . If all the neighbours are in the opposite type (i.e. if  $s_i = 0$  and  $o_i \neq 0$ ),  $Q_i = 1$ . As the initial spatial configuration is randomly chosen, the initial distribution of  $Q_i$  is binomial.

Table 1: Ratio between the number of neighbours of opposite type to the social degree:  $Q_i = \frac{o_i}{o_i + s_i}$ . Coloured values: agent  $a_i$ , will be satisfied if  $Q_i$  is under the *tolerance* threshold 0.37

$\begin{smallmatrix} o \\ s \end{smallmatrix}$	0	1	2	3	4	5	6	7	8

7	0	.125							
8	0								

In this model, all the agents have the same threshold of tolerance: it is a constant value (noted *tolerance*) which is fixed before the run. So, at each time  $t$ , for each agent  $a_i$ , equation 1 becomes:

$$satisfied_i(t) = (Q_i(t) \leq tolerance) \quad (6)$$

The agents are said tolerant if the tolerance is greater than 0.5 ( $0.5 \leq tolerance$ ) and intolerant otherwise. We use the *Moore* neighbourhood commonly employed in agent-based models. So the neighbours of an agent are those living in the eight nearest cells surrounding him and the degree  $d_i$  is a number between 0 and 8. For instance, if the *tolerance* threshold is 0.37, one particular agent  $a_i$ , at time  $t$ , will be satisfied if  $Q_i(t)$  is under this value; this happens in the following eighteen cases: ( $o_i = 0$ ), ( $s_i = 2, o_i = 1$ ), ( $s_i = 3, o_i = 1$ ), ( $s_i = 4, o_i = 1$ ), ( $s_i = 5, o_i = 1$ ), ( $s_i = 6, o_i = 1$ ), ( $s_i = 7, o_i = 1$ ), ( $s_i = 4, o_i = 2$ ), ( $s_i = 5, o_i = 2$ ) and ( $s_i = 6, o_i = 2$ ) (see the coloured values on table 1). More, if there are exactly eight neighbours, i.e.  $d_i = 8$ , (see table 1, the diagonal line) such a tolerance means that the agents are intolerant and cannot suffer more than two opposite neighbours.

**How do unsatisfied agents move away ?** In standard Schelling's models agents move only to satisfy their own interest. This requires that agents must be able to access distant information in order to determine whether or not it will be satisfied in a new vacant cell. This kind of behaviour is characteristic among economical agents that seek to maximize their gain. Nonetheless such a behaviour come out of the idea of agents acting approximately rational, rather economically rational in terms of utility and breaks down the *principle of locality* (see Brownlee (2007)).

**Global behaviour** Regarding the micro-macro problem-atic, the Schelling model provides examples for the two

cases:  $[i \rightarrow S]$  and  $[\bar{i} \rightarrow S]$  where  $i$  (resp.  $\bar{i}$ ) stands for individual intolerance (resp. tolerance) and  $S$  stands for a high degree of global segregation. While the first case is the intuitive situation where micro-intolerance induces macro-segregation, the second case is more surprising as it shows that tolerant behaviours can nonetheless induce a global segregation.

## The Schelling Model with the *Eulogy to Fleeing* rule

In standard Schelling's models agents aspire to satisfy their interests in the new places they move in. In this section, we rather assume a reaction from agent without real cognitive abilities expressed by the simple *Eulogy to Fleeing* rule (EF rule).

### The *Eulogy to Fleeing* rule

The *Eulogy to Fleeing* rule is agreeing with the definition of the term *satisficing* proposed by Herbert A. Simon (1956). "Satisficing describes the selection of a good enough solution, the selection of a decision that meets a minimum threshold or aspiration level, the selection of which occurs in the context of incomplete information or limited computation" Brownlee (2007).

The EF rule is defined as follows: *for each unsatisfied agent, a cell is randomly chosen 'all over the world' and the agent moves to this cell if and only if it is vacant*. So the agents may move at random towards a new location according to their preferences by allowing utility-increasing or utility-decreasing actions. Moves do generate new satisfied or unsatisfied agents by a chain reaction until an equilibrium is reached. At a time  $t$ , if all the agents are satisfied, the EF rule has no effect and then such a configuration is a *fixed point* for the dynamics.

This simple rule is more in the spirit of the complex system paradigm, and, as locally there is no seeking for immediate benefits, it is interesting to know its global consequences. Although it is easy to build some particular cases where the EF rule does not converge, in the following simulations this rule leads the system towards an equilibrium. Let's note that although similar rules based on a random choice of vacant locations are already proposed (Edmonds and Hales (2005), Izquierdo et al. (2009)), they do not look completely identical to the EF rule. In particular, with the EF rule, an unsatisfied agent may stay in place for a while if the randomly chosen locations are occupied.

### Simulation and results

In this paper, all the simulations are realized in the *Net-Logo*<sup>1</sup> multiagent programmable modeling environment Pham (2004), Wilensky (1999). For each simulation, the agent's features are updated in an asynchronous way and

<sup>1</sup><http://ccl.northwestern.edu/netlogo/>

the global geographic parameters are fixed. The world is a square of locations horizontally and vertically wrapped. An agent with type 'yellow' (resp. green) is represented by a yellow (resp. green) square. A black square represents a vacant location. A simulation stops at convergence, when all the agents become satisfied.

The world is a grid-square composed of 10000 locations. This size is a good compromise between the necessity to have a large value to avoid small space effects and the convenience to have a small value to achieve short computation time. There are 1000 vacant locations, knowing that the *density rate* is 90% and 4500 agents in each type. We imposed a random initial configuration: in the cases studied below, the value of  $s_{rand}$  is indistinguishable from 0.5; thus initial configuration induces an *aggregateIndex* closed to 0.

We conducted two types of experiment: in the first one, all the agents are *intolerant* and in the second they are *tolerant*.

**Intolerant agents** For this first experiment the *tolerance* is set to 0.37 (see table 1); so all the agents are intolerant. We can see in figure 1 the result of the agents spatio-temporal evolution at the end of a representative run: after 1150 steps all the agents are satisfied (i.e. *satisfactionRatio* = 1), the mean  $Q_i$  over the whole population (noted  $\bar{Q}$ ) is 0.024 and the *aggregateIndex* is 0.957. From 100 independent runs we obtain, a mean of 0.952 (0.0041)<sup>2</sup> for the *aggregateIndex* and 0.024 (0.0022) respectively for  $\bar{Q}$ . We can observe the emergence of large spatial homogeneous patterns. Moreover the borderland between the patterns is almost build with every vacant location (black square). So patterns are isolated by a *no-man's-land* of vacant cells.

**Tolerant agents** Here, the goal is to show that segregation occurs even if no agent strictly prefers this. We set the *tolerance* to 0.63 (see table 1), so all the individuals are tolerant. In particular, if an agent has exactly eight neighbours, it can bear up to five opposite agents in its vicinity. Figure 2 gives an example of the evolution of the agents' locations during a representative run. At the end, after 228 steps, all the agents are satisfied, the mean  $Q_i$  over the whole population is 0.229 and the *aggregateIndex* is 0.548. From 100 independent runs we obtain, a mean of 0.53 (0.0119) for the *aggregateIndex* and 0.233 (0.0094) respectively for  $\bar{Q}$ . While spatial segregation is not an attribute of the rational individuals's behaviour, we can observe the emergence of many segregationist patterns, although they have a smaller size that in the previous case (see figure 1). More, vacant locations are scarce on borderline because with a high tolerance level vacant cells are not requisite to delimit segregationist patterns.

<sup>2</sup>standard deviation is shown in ()

Figure 1: The Eulogy of Fleeing rule: *tolerance* = 0.37  
View at convergence (*ticks* = 1150):  $\bar{Q}$  = 0.024  
*aggregateIndex* = 0.957

## Discussion

In this section, we have shown that in spite of the use of a more simple and realistic local rule, the model produces a comparable global behaviour than the classical Schelling model.

We have shown that both intolerant and tolerant local behaviours lead to the satisfaction of all the agents with the emergence of global segregationist patterns. Moreover, the gap between the *tolerance* and the mean  $Q_i$  over the whole population is surprisingly large at the end of a run. In this way complex dynamics build much more liveable configurations than necessary. With intolerant agents, vacant places are required to form the frontiers and insulate agents in homogeneous patterns. In the next section, we propose to modify the model in order to insulate segregationist patterns without using vacant locations mainly.

## From *no-man's-land* to *mediator-land*

Most often, in real life some individuals are tolerant whereas others are intolerant. In a model, there are two ways to take into account this fact: either fixing a distribution for the tolerance, or dynamically evolving tolerance to 'converge' toward a particular distribution. The first solution requires not only to choose one distribution: *uniform*, *normal*, *poisson*,... but also to fix its parameters: mean and standard deviation.

Figure 2: The Eulogy of Fleeing rule:  $tolerance = 0.63$   
View at convergence ( $ticks = 228$ ):  $\bar{Q} = 0.229$   
 $aggregateIndex = 0.548$

### Adaptive local rule

As we have no *a priori* on a target level of tolerance, we choose to start from an intolerant configuration and to apply a local rule to gradually increase the tolerance. For instance, when a person is immersed in an unknown world, his first attempt will be to meet people which look like him; so initially, certainly with many *apriority*, such a person is gregarious or intolerant. Then, if his requirement is too high relatively to the environment, it will be difficult for him to find a fitting place; therefore a natural tendency will be to gradually reduce his stress by decreasing his gregariousness and/or increasing his tolerance.

In this new instance of the GMS, each agent has its own tolerance threshold. Furthermore, each individual threshold may vary over time. So, for each agent  $a_i$ , at each time  $t$ , the *satisfied* indicator (see equation 1) becomes:

$$satisfied_i(t) = (Q_i(t) \leq tolerance_i(t)) \quad (7)$$

Initially, the tolerance of each agent is set to a very small value, therefore an agent is at first radically intolerant and so will be unsatisfied. At each time, for each unsatisfied agent, a cell is randomly chosen 'all over the world' in order to move in if it is vacant, otherwise, i.e. if the cell is already occupied, the agent stays put and adapts its own *tolerance* to the context by increasing its value with a small increment.

### Simulation and results

For each agent, the *tolerance* is initialised to 0.001 and we chose a small increment of 0.003. We can see on figure 3 the spatio-temporal evolution of the agents at the end of a representative run. After 663 steps all the agents are satisfied; the mean *tolerance* over the population is 0.365, the mean  $Q_i$  over the population is 0.049 and the *aggregateIndex* is 0.892. Even if dynamics are more complex than in Schelling's model, we can observe the emergence of spatial homogeneous patterns yet. On 100 runs we obtain, a mean of 0.919 (0.0120) for the *aggregateIndex* and 0.360 (0.0047) respectively for the mean *tolerance*. So, on average, dynamics lead agents to remain intolerant and a high segregation emerges at the global level; once again this is an example for the case  $[i \rightarrow S]$ .

Figure 3: Dynamic tolerance  
View at convergence ( $ticks = 663$ ):  
 $aggregateIndex = 0.892$  mean  $tolerance = 0.365$

We can observe that the frontier between homogeneous patterns is constituted both by vacant cells (black square) and by the most tolerant agents (white circle), i.e. agents with  $tolerance \geq 0.39$ ; therefore, for a significant part, homogeneous regions are isolated by *places for mediation* where opposite agents may co-exist. We can note that there are also tolerant agents outside the *mediator-land*; this corresponds to *scoria*<sup>3</sup> in some areas where former conflicts have led to the local hegemony of one of the two types; thus data collected from the own tolerance of the agents allow to learn

<sup>3</sup>Scoria is the dross that remains after the smelting of metal from an ore

more about the past of the system.

## Discussion

A first result is that dynamics leads the mean tolerance toward a relatively weak value (0.36); as a consequence, when all the agents become satisfied, they remain on average intolerant. The second result is that segregation is still high (0.919). The third result is that in a world where agents are on average intolerant there are some tolerant agents which play a crucial role in the spatial distribution. This can serve as a clue to extend the model toward more *mosaic-like* structure. *Type-mix* would be favoured by the existence of secluded agents amidst individuals having an opposite type. In the present model, this is impossible because agents are not tolerant enough to endure such a situation: we have to enhance the dynamics to allow tolerance to reach high values. On the contrary, the presence of *scoria* shows that one agent with high tolerance may be useful in a moment at a place then becomes superfluous later in the same location; so decrease the tolerance of satisfied agents may help to avoid such 'frozen region'. All this suggest us to manage two antagonist dynamics: increasing and decreasing the tolerance; so, we expect to significantly lower the level of segregation while maintaining a weak mean tolerance.

### How to avoid high segregation ?

In this last section the goal is to respond to the question: *How intolerant agents can become satisfied without the emergence of macro segregation?*

In the new model we propose, there are two antagonist dynamics, the first one increases the tolerance of unsatisfied agents, whereas the second decreases the tolerance of satisfied agents. Initially, the agents have a weak tolerance and are thus radically intolerant and unsatisfied.

- An unsatisfied agent, can either move to a vacant place or else simply increase its tolerance (for details, see the previous section).
- Conversely, for a satisfied agent  $a_i$ , if the difference  $\delta$  between its  $\text{tolerance}_i$  and the value of  $Q_i$  in the place it lives in is too high, its tolerance decreases.

In real life, when a person is no longer confronted with distressing circumstance, his ability to cope later in such a situation is reduced. This phenomenon can be explained by a mechanism of *forgetfulness*. In the model, an agent is satisfied if it is not faced to a large enough number of opposite agents. If over time such a lack of confrontation persists, then the agent gradually reduces his threshold of tolerance.

### Parameter space exploration

There are two main parameters that control the dynamics of tolerance: the amount of increment  $\text{inc}$  and decrement  $\text{dec}$ .

First we conduct a parameter space exploration in order to choose suitable values for the simulation.

In the context of complex systems, most often there are several parameters which together determine the global dynamics. In order to choose values for the parameters used in the simulations, we have first conducted an exploration of the *parameter space*. The objective to minimize both the mean *tolerance* and the global *aggregateIndex* is difficult because when the first one decreases, the second increases and conversely. Therefore, we conduct a tradeoff-analysis to identify compromise for which the two criteria are mutually satisfied in a *Pareto-optimal* sense. This is a typical multi-objective optimisation problem where the optimal solutions correspond to a set of compromises expresses by a *Pareto front* Dyer et al. (1992), Belton and Stewart (2002). In practice, the Pareto front is proposed to a human decision-maker who then chooses a solution according to his expertise.

For all the tests we perform, the parameter  $\delta$  is set to 0.1. We focus our effort on areas that lead to interesting regions where convergence occurs with low *tolerance* and low *segregation*: each test corresponds to one couple ( $\text{inc}$ ,  $\text{dec}$ ) in the range  $[0.025, 0.040] \times [0, 0.030]$ . There are 60 tests and, for each one, results are averaged over 100 runs. Each data point of the scatter plot (see figure 4) corresponds to a couple ( $\text{inc}$ ,  $\text{dec}$ ) and represents both the *aggregateIndex* (y-value) and the mean *tolerance* (x-value) obtained when all the agents are satisfied. We can observe that heightening the parameter  $\text{dec}$  (while  $\text{inc}$  remains constant) pushes the point solution to the left toward the *Pareto front*. Conversely, lowering the parameter  $\text{inc}$  (while  $\text{dec}$  is constant) moves up the point solution on one front. This analysis leads us to choose a particular point on the *Pareto-front* that represents a good compromise between both intolerance and low segregation. To conduct the following simulations, we choose the point corresponding to the parameter values  $\text{inc} = 0.029$  and  $\text{dec} = 0.017$  (See the arrow on figure 4).

## Results

Initially, all the tolerances are set to 0.1. We can observe on figure 5 the spatial configuration at the end of a representative run when all the agents are satisfied: after 513 steps, the mean  $Q_i$  over the population is 0.306, the mean *tolerance* over the population is 0.369 and the *aggregateIndex* is 0.383. On 100 runs, we obtain on average an *aggregateIndex* of 0.388 (0.0110) and a mean *tolerance* of 0.370 (0.0048). The value for the *aggregateIndex* (0.388) has to be compared with the ones obtained with the two previous models (0.957 and 0.919)

The frontier between homogeneous patterns is constituted by the most tolerant agents and there is no *scoria* inside the patterns. One observes that homogeneous areas are infiltrated by many secluded individuals: there are some niches which co-exist within a cohort of unlike agents; this is possible only because loners are very tolerant. In contrast with

Figure 4: Parameter space analysis  
Tolerance vs. Segregation

the previous models, vacant locations don't play any role in isolating individuals from each other. The most important feature of this model is that it prevents intolerant agents from high segregation. As the Schelling's model provided an example for the case  $[i \rightarrow S]$ , this model exemplify the  $[i \rightarrow \bar{S}]$  micro-macro link.

### Conclusion and future work

In this article, we have proposed to extend the Schelling's model considering that every individual has its own tolerance level. In a first step we have proposed a simple way to locally manage the tolerance; all that gives rise to the emergence of a new kind of border and inner *scoria* both made up of the most tolerant agents. In a second stage, we have introduced new dynamics that consists of combining two antagonist strengths. As a result of this confrontation, the agents are able to reach an equilibrium where they all are satisfied, rather intolerant, but where the aggregation level remains low. As, at our knowledge, there is no prior work on this topic, this result is a significant challenge to the analysis conducted by Schelling: it shows that one can avoid segregation if the tolerance level is adaptive, which is in our opinion a better assumption.

In future work, we will revisit those results by considering situations closer to reality. Beyond a simple world of agents embedded on an homogeneous toroidal-grid, we have to consider different types of network as for example neighbourhoods defined from a scale-free network. We have observed the emergence of very different type of frontiers: *no-man's-land*, *mediator-land* or in some extend *mixing*; thus,

Figure 5: Intolerant agents avoid global segregation  
View at convergence (*ticks* = 513): mean  
*tolerance* = 0.369, *aggregateIndex* = 0.383

it might be interesting to study for a border, its composition, its spatial distribution, its volume, porosity, permeability,... and so to better understand its function: place of exchange and/or medium to isolate.

## Abstract

Although in the last few decades a variety of theoretical tools have been developed to better understand living organisms, their impact on experimental research has been rather limited. A common element between these theories is the idea of metabolic closure, i.e., the systems that produce all their metabolites and catalysts. In spite of an increasing consensus on the relevance of closure, a formal and operative definition has remained elusive. In this paper we revisit RAF sets and chemical organization theory and show how these two theories overlap and could help bring forth real world results. We also state a theorem ensuring the presence of a cycle of interdependent catalysts for RAF sets and conjecture that these cycles give stability to the network. This conjecture is illustrated and supported by computer simulations. Unavoidably, our viewpoint introduces the notion of fluxes and thus a temporal dimension to the purely algebraic model of RAF sets. The results of this work show that the incorporation of closure, topological and dynamical tools altogether is a promising path for a deeper understanding of living systems.

## Introduction

In the last thirty years there have been many efforts directed to develop theories to understand biological systems in terms of metabolic closure or, equivalently, systems that produce and maintain themselves. Two crucial models that definitively put metabolic closure at the very center of biological organization are: Autopoiesis, formulated by Maturana and Varela (Maturana and Varela, 1980), and Rosen's ( $M, R$ ) Systems (Rosen, 1958). But these two theoretical studies and similar theories (like the Chemoton or Autocatalytic sets), although very clarifying in basic aspects, have not yet produced technical results that illuminate the daily life of bench biologists involved in experimental research.

In the past (Jaramillo et al., 2010) we have emphasized that a little known formalism called RAF sets (Hordijk and Steel, 2004) is a particularly suited technical tool to understand closure in general and autocatalytic sets in particular. Here we study the relation between RAF sets and the chemical organization theory (COT), which is a theory that

adds to the dynamical aspects by introducing the notion of metabolic fluxes to the purely algebraic vision of RAF sets, an idea deeply embedded in basic metabolic engineering. This is accomplished by expressing the kinetic behaviour of the components (molecules) in terms of a stoichiometric matrix, which then leads directly to the concepts of rates and fluxes, introducing the temporal dimension. This approach can be used to expand the original RAF sets theory, which we consider to be highly valuable for biology, but unfortunately too algebraic to be of use, in particular lacking a way to describe the time behaviour of the systems, which is of most importance in the direction of a more realistic biological context.

Here we will show how notions from chemical kinetics can be fused with RAF sets to search for closure in metabolic networks. Although the results presented here seems, initially, as a mere technicalities without theoretical relevance, they open new research paths as we adjoint highly theoretical notions (RAF set and the metabolic closure) with an accepted used tool to understand metabolism in steady state. In particular we show the logical relation between COT and RAF sets.

## RAF sets and COT in a Nutshell

We now give a brief introduction to the work of Hordijk and Steel (2004), who came up with a formal framework to study a autocatalytic systems. Their main aim appears to have been to develop algorithms with which autocatalytic systems in Kaufmann's sense (1993) could be described and found computationally. They have produced a powerful approach that can be used to analyze a wide variety of systems. Their formalism is based on the following two important sets:  $X$  is the set of molecules involved in metabolism (i.e. metabolites, catalysts or external input material, termed *food set* in the formalism), and  $\mathcal{R}$  is the set of reactions that define the metabolic network. Each reaction  $r$  is represented as a tuple  $(A, B)$ , where  $A, B \subset X$ ,  $A \cap B = \emptyset$ ,  $A$  are the reactants and  $B$  the products of reaction  $r$ .

Further, to formalize the notion of catalysis, a specific set  $C$  (called the set of "catalyzations" by Hordijk and Steel)

<sup>‡</sup>All authors contributed equally

is introduced. Each catalyzation  $c$  is a tuple  $(x, r)$ , where  $x \in X$  is the catalyst and  $r \in \mathcal{R}$  is the reaction catalyzed by  $x$ . Additionally, the subset of molecules that are used but are not produced by metabolism is called food and denoted by  $F$ . Thus, a *catalytic reaction system* over a food source  $F$  is composed by a triplet  $\mathcal{L} = (X, \mathcal{R}, C)$  which defines the universe of molecules ( $X$ ), the reactions occurring among these molecules ( $\mathcal{R}$ ) and the identity of the catalyst involved in each reaction ( $C$ ). Note that this already provides, although at a very simple level, a way to refer to a system, and distinguish the inner and outer components and the transformations that the components undergo.

The following additional functions are defined:  $\rho(r) = A$  and  $\pi(r) = B$ , which return the reactants and the products of any given reaction  $r$ , respectively, and the function  $\text{supp}(r) = \rho(r) \cup \pi(r)$ . With the help of these elementary functions, the same notion can be extended to a *set of reactions*  $\mathcal{R}'$  as  $\rho(\mathcal{R}') = \bigcup_{r \in \mathcal{R}'} \rho(r)$ , where  $\mathcal{R}' \subseteq \mathcal{R}$ . This definition captures the conglomerate of molecules that participate as reactants for a set of reactions. A similar definition holds for  $\pi(\mathcal{R}')$ , the products of a subset of reactions. With these ideas we can define the closure of a subset  $X' \subseteq X$  relative to  $\mathcal{R}' \subseteq \mathcal{R}$  ( $\text{cl}_{\mathcal{R}'}(X')$ ) as the set of reachable molecules that can be synthesized by starting from  $X'$  and iteratively applying all the reactions in  $\mathcal{R}'$ . Note that this definition is of most importance, as it follows that a set of molecules which is closed (i.e. it is equal to its closure) under a set of reactions will not generate any new molecule and thus, conserves its identity. This operation captures the central idea of metabolic closure, which is fundamental for achieving organizational invariance in autopoietic systems. A *catalytic reaction system* is *reflexively autocatalytic* if for each  $r \in \mathcal{R}$  there is an  $x \in \text{supp}(\mathcal{R})$  such that  $(x, r) \in C$ . In other words, every catalyst must be a reactant or product of a reaction in the same system. The system is *F-generated* if every reactant is either produced by the system or incorporated as a food item (i.e. formally  $\rho(\mathcal{R}) \subseteq F \cup \pi(\mathcal{R})$ ). A system that is *reflexively autocatalytic* and *F-generated* is called a *RAF set* (see figure 1).

RAF sets can be understood informally as an interdependent set of biochemical reactions where all of the metabolites, with the exception of the so-called food set, are produced by the collection of reactions  $\mathcal{R}$ . This self generation, a defining feature of autopoietic and  $(M, R)$  systems, is the core of metabolic closure. Thus, RAF sets, autopoietic and  $(M, R)$  systems overlap to a great extent; positioning RAF sets as an operative theory to metabolic closure. The advantage of RAF set formalism is that it is precise enough to be coded in well defined algorithms that exploit its intrinsic recursiveness. To check if a given collection of biochemical reactions is indeed a RAF set, Hordijk and Steel (2004) developed algorithms aimed to analyze the interdependence between a given catalyst and its production pathway.

The chemical organization theory, initially developed by

Dittrich and Di Fenizio (2007), deals with chemical reaction networks. In what is called *static analysis*, the part of this theory that is concerned with the topology of the system, molecules and reactions are defined in a very similar way as in RAF sets. Most notably, both theories share the definition of the closure operator. But while COT makes no explicit mention to catalysts and therefore distances itself from biological systems in which this concept is fundamental, it does incorporate tools to study the dynamical behaviour of chemical reaction networks, thus provides a connection between the structure of a system and the dynamical aspects of it. This is accomplished by first expressing the system in terms of the stoichiometric matrix and associated differential equations.

In COT, it is useful to recognize systems fulfilling certain properties, such as closure. For example, a system is self-sustained if it is able to generate every molecule that is used up. When this topological consideration is transported to the time domain, we can define mass-maintaining systems. A system is said to be mass-maintaining when:

1. All reactions that can be fired by the molecules in the system occur at some positive rate
2. Reactions whose reactants are missing from the system do not occur
3. There is a combination of reaction rates such that all molecules increase or maintain their concentration.

A system which is both closed and mass-maintaining is called an organization. Organizations are interesting as they resemble very closely autopoietic systems. Also, organizations are at the center of many theorems in COT. This theory and RAF sets deal with closure. While one makes no distinction between catalysts and metabolites, the other one lacks the notion of time, which are essential elements of living systems. In the next paragraph we will show an relation between these two theories.

## Kinetics in RAF sets

If a theory is to have impact on real biochemical world, it must deal with the notions of that domain, thus, to gain a full understanding of closure we must complement the purely algebraic nature of RAF sets with ideas taken from Metabolic Control Analysis (MCA), a field generated to understand and measure fluxes in biochemical systems which is of common use in the field of metabolic engineering.

Current MCA is a quantitative theory that does not consider closure, as catalysts (i.e. enzymes) are placed in the network, but the reactions generating them are not taken into account. By putting the quantitative aspects of MCA and applying them to RAF sets, side by side, we can gain insight in how to study closure quantitatively. All the theories of metabolic closure (Autopoiesis,  $(M, R)$  systems, Autocatalytic sets, etc) are essentially algebraic or conceptual

Figure 1: A simple example of a RAF set. Food elements  $F$  are incorporated into the system and generate metabolites  $M$ , which are transformed into two different catalysts sets: a)  $T_{in}$  which regulates the inflow of  $F$  and  $C_2$  which catalyzes its generation and b)  $T_{out}$  which regulates the outflow of waste metabolites  $W$  and  $C_1$  who catalyzes its formation. In addition,  $C_1$  and  $C_2$  catalyze the formation and destruction of the transporter catalysts ( $T_{out}$  and  $T_{in}$ , respectively), and also they mediate the generation and consumption of each other, forming the Reflexive Autocatalytic core of the system. Finally, growth is regulated by modulating the inflow of  $F$  and the outflow of  $W$ . We want to highlight the loop defined by metabolites  $M$  which turn into  $C_2$  who regulates the formation of  $C_1$  starting from  $M$ , a reaction regulated by  $C_2$ .

models centered on connectivity but not in dynamics. To go further in our understanding we must include the time course evolution of the concentrations inside the system.

Fortunately, the formalism of Reder (1988) that uses the stoichiometric matrix and the matrix  $D_x v$  to study rates, can be applied almost *verbatim* to analyze if a RAF set will grow or disappear. The great advantage of applying MCA formalisms is that we can quantitatively study how a system with metabolic closure can grow or disappear.

RAF sets are sets of coupled biochemical reactions with the attribute that the catalytic dependences between reactions and their catalysts are explicitly given. As said, RAF sets demand that almost all the molecules that conform a system can eventually be generated, directly or indirectly, from certain food materials and that all catalysts are produced by the system.

The *transformation* part of a RAF set can be represented by the formalism of the stoichiometric matrix, a well known tool extensively used in fields like MCA and Systems Biology in which every reaction is written as a column and every metabolite is referred to as a row. For example, the matrix  $N$  of the system described in figure 1 would be as following:

$$N = \begin{pmatrix} 1 & -1 & -1 & -1 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & -1 \\ 0 & 1 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & -1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \end{pmatrix}$$

By using the column representation of reactions, it is convenient to define the addition of reactions as a standard addition operation of vectors. This operation expresses the occurrence of both reactions as a single net reaction.

Note that the *catalytic* part lies outside the stoichiometric matrix and cannot be deduced from it. But, in an idea that can be traced back at least to Reder (1988), the *catalytic* part can be represented by a matrix  $D_x v$  (also known as the Jacobian of the system) that contains all partial derivatives relating every reaction with every metabolite (or catalyst) in the system. Thus, the catalysts for a given reaction can be discovered by ranking the partial derivatives of the rate of this reaction respective to all metabolites (molecules) in the system. For example, the Jacobian matrix  $D_x v$  of the system described in figure 1 would be:

$$D_x v = \begin{pmatrix} \partial_M v_1 & 0 & 0 & 0 & \partial_{T_{in}} v_1 & 0 \\ \partial_M v_2 & 0 & \partial_{C_1} v_2 & \partial_{C_2} v_2 & 0 & 0 \\ \partial_M v_3 & 0 & \partial_{C_1} v_3 & \partial_{C_2} v_3 & 0 & 0 \\ \partial_M v_4 & 0 & \partial_{C_1} v_4 & 0 & \partial_{T_{in}} v_4 & 0 \\ \partial_M v_5 & 0 & 0 & \partial_{C_2} v_5 & 0 & \partial_{T_{out}} v_5 \\ 0 & \partial_W v_6 & \partial_{C_1} v_6 & \partial_{C_2} v_6 & 0 & 0 \\ 0 & \partial_W v_7 & \partial_{C_1} v_7 & \partial_{C_2} v_7 & 0 & 0 \\ 0 & \partial_W v_8 & 0 & \partial_{C_2} v_8 & \partial_{T_{in}} v_8 & 0 \\ 0 & \partial_W v_9 & 0 & \partial_{C_2} v_9 & 0 & 0 \end{pmatrix}$$

Every RAF set can then be described by two matrices;  $N$ , that shows the network connectivity, and  $D_x v$ , that quantifies catalyzations.

The necessity of using the  $D_x v$  matrix to analyze RAF sets lies in the fact that autocatalysis is a phenomenon that does not depend *only* on connectivity. As it has been shown recently by Plasson et al. (2010) and Piedrafito et al. (2010), the stability of an autocatalytic set depends on the relative rate of some reactions. Thus, two systems with identical connectivities but with different kinetics for some reactions can have vastly different behaviors.

As stated above, another theory concerned with formalizing biological organization is COT, a theoretical framework also centered in the idea of closure differing from RAF as the idea of catalyzation, perhaps the hallmark of RAF sets, is not considered. On the other hand COT brings an idea, the importance of fluxes in a network, that are not considered in RAF sets which is a purely algebraic approach to the description of biological organization. Thus an important question arises: can these two models be related? Can they support each other, in the sense of across fields fertilization? In the next section we clarify some relations between these two models.

An observation needed at the very beginning is that analysis using RAF sets and COT belong to two very different viewpoints as crucial elements in one theory are totally absent in the other. Thus as organizations (in the sense of COT) require that the overall flux across a relevant subset of reactions is maintained (thus avoiding the disappearance of crucial metabolites that, if absent, will produce network collapse). A mirror like situation can be stated with respect to catalyzations, a cornerstone idea in RAF sets, and (surprisingly) an idea that is absent from COT. Thus we should expect that if a system is a RAF set it is not immediate that it is also an organization. Only in some especial conditions we should be able to find how these ideas can be concurrently applied.

## A hidden relation between RAF sets and COT

A further dissection of RAF sets shows that, although fluxes and reaction rates initially seem to be absent from this model, kinetic ideas do exist just below the surface. In effect we propose two lemmas and a theorem that will bring new light to the problem of comparing both approaches:

**Lemma 1** *If a catalytic reaction system  $\mathcal{L} = (X, \mathcal{R}, C)$  is  $F$ -generated, then for all metabolites  $x$  (including catalysts) produced by any reaction  $r \in \mathcal{R}$ ,  $x \in \text{supp}(\mathcal{R})$  there is a positive linear combination of reactions  $\bar{r}_x = \sum_i \alpha_i r_i$  such that the metabolite  $x$  belongs to the products of the reaction  $\bar{r}_x$ ,  $x \in \pi(r_0)$  and the reactants of  $\bar{r}_x$  belong to the Food set, i. e.,  $\rho(r_0) \subseteq F$ .*

**Proof:** Considering the algorithm used to find the closure of  $\mathcal{L}$  (Hordijk and Steel, 2004), let  $W = F$ . Then add

the products of reactions  $\mathcal{R}_0 = \{r \in \mathcal{R} | \rho(r) \subseteq W\}$  to  $W$ . Adding all reactions in  $\mathcal{R}_0$  gives a global net reaction  $\bar{r}_0$  that consumes metabolites from the Food set  $F$  only and produces each metabolite in  $W$ . If this process is repeated, considering  $W = F \cup \pi(\mathcal{R}_0)$ , it is possible to build the set  $\mathcal{R}_1$  that contains all reactions that have their reactants in  $W$ , but excluding the reactions from  $\mathcal{R}_0$ . Adding all reactions in  $\mathcal{R}_1$  we obtain a new reaction  $\bar{r}'_1$  that requires metabolites from  $W$  only and produces any metabolite in  $\pi(\mathcal{R}_1)$ . To obtain the fact that this last reaction uses only metabolites from the Food source, let  $\bar{r}_1 = \alpha \bar{r}_0 + \bar{r}'_1$ , where  $\alpha$  is the most negative stoichiometric coefficient of the reaction  $\bar{r}'_1$ . This procedure takes enough metabolites from  $F$  to generate  $\pi(\mathcal{R}_1)$ . If we repeat this algorithm until it is not possible to find new metabolites, we will have generated  $cl_{\mathcal{R}}(F) = W$ . If the system is  $F$ -generated, according to Hordijk and Steel (2004), we have that  $cl_{\mathcal{R}}(F) = F \cup \text{supp}(\mathcal{R})$ . We have shown that for every metabolite  $x \in cl_{\mathcal{R}}(F)$  a composite reaction exists which generates it consuming food items only, in fact it is one of the  $r_i$ .

**Lemma 2** *If a catalytic reaction system  $\mathcal{L} = (X, \mathcal{R}, C)$  is  $F$ -generated, there is a strict positive linear combination of reactions  $\hat{r} = \sum_i \alpha_i r_i$  with  $\alpha_i > 0$  such that all metabolites are products of this reaction, i. e.,  $\hat{r}$  is a strictly positive vector.*

**Proof:** From Lemma 1 it follows that for each metabolite  $m_j$  there is a positive linear combination of reactions  $\bar{r}_{m_j} = \sum_i \alpha_{i,j} r_i$  such that this metabolite is produced exclusively from the Food set. This linear combination  $\bar{r}_{m_j}$  is the resultant net reaction associated with the path of reactions  $j$  that generate each metabolite  $m_j$ . If for all metabolites we add their generating reactions  $\bar{r}_{sum} = \sum_i \alpha_i r_i$  with  $\alpha_i = \sum_j \alpha_{i,j}$ , we have from the Lemma 1 that  $\bar{r}_{sum}$  is strictly positive. We must note that not all reactions will be used. We refer to these reactions generally as  $r_s$ , having  $\alpha_s = 0$  in  $r_{sum}$  for those reactions. If we consider the sum of these reactions  $r_{not} = \sum_s r_s$ , it will consume metabolites. To maintain  $\hat{r}$  positive and still fire these non-essential reaction (this will be needed later), we set  $\hat{r} = \beta r_{sum} + r_{not}$  with  $\beta$  sufficiently large. Then we can construct a strictly positive linear combination  $\hat{r} = \beta r_{sum} + r_{not} = \sum_i \bar{\alpha}_i r_i$  with:

$$\bar{\alpha}_i = \begin{cases} 1 & \text{if } r_i \in \{r_s\} \\ \beta \alpha_i & \text{if } r_i \notin \{r_s\} \end{cases} \quad \text{note } \bar{\alpha}_i > 0$$

and all the metabolites are product of this reaction  $r_0$ .

These lemmas, framed completely in the language of RAF sets, could be interpreted as mere technical results about RAF sets. In essence they state that every metabolite can be generated from the food set and makes explicit the overall reaction producing each, non-food, metabolite. But every time we use a stoichiometric matrix  $N$  we are implying a given kinetics because of the necessary equation

relating  $N$  to the change of concentrations:  $N \cdot v = dX/dt$ , where  $v$  is the vector of rates. Thus the requirement, in COT, that  $(dX/dt \geq 0)$  can be phrased as a condition on the components of  $v$ . These lemmas show how some (not all) Organizations could be RAF sets, and it is interestingly that they are proved by using notions of linear algebra. Also note that the positive linear combination predicted by the lemmas explicitly shows how to combine individual reactions in any RAF set to attain mass-maintenance.

Once we have established this link we can a little bit further and search for deeper connections. The next theorem continues to exploit matrix  $N$  to sketch how some RA sets are F-generated using the stoichiometric matrix  $N$ .

**Theorem 1** *If a catalytic reaction system is F-generated, then there is a strictly positive rate vector  $v$ , such that  $N \cdot v = dX/dt$  is also strictly positive, where  $N$  is the stoichiometric matrix of the system.*

**Proof:** We note that the operation  $N \cdot v = dX/dt$  is equivalently mathematical to make a linear combination of reactions  $r = \sum_j \alpha_j r_j$  if we consider each reaction as a column and  $\alpha_j$  as the velocity of reaction  $r_j$ . From Lemma 2, if we take the reaction  $r_0$  and choose  $v_j = \bar{\alpha}_j$  (normalizing time units), therefore a  $v$  exists with components  $v_j > 0$  associated to a flux vector  $dX/dt$  that satisfies  $dX_i/dt > 0$ , equivalent to the column representation of  $r_0$  with all of their components also positive.

**Corollary 1** *If a catalytic reaction system is F-generated, then it is also an organization.*

**Proof:** An F-generated system is, by definition, *closed* and as theorem 2 shows, it also satisfies the property of *mass-maintenance*. Thus, it is an organization.

This theorem explains the existing relations between Organizations, F-generated sets, RA sets and RAF (see figure 2). Essentially, we have proved that all F-generated sets are *organizations* and a subset of them are also *reflexive autocatalytic*. This subset is the RAF sets. Theorem 1 is a simple one that has the virtue of illuminating how these two theoretical frameworks are related to each other.

This result is important because some new technical theorems have been obtained by Dittrich's group, for example, on how to detect organizations among real metabolic networks (Centler et al., 2010, 2008). Thus, our theorem shows that these new tools, developed to find organizations, could be also used to search for RAF sets.

In addition, we will make a definition to the sets that are organizations and RA at the same time.

**Definition 1** *If a catalytic reaction system is Reflexive Autocatalytic and an Organization, then it is a Reflexive Autocatalytic Organization, RAO.*

These sets are reaction systems that can be sustained, but not necessarily can be generated from a food set  $F$  exclusively. We have shown that all F-generated sets are orga-

Figure 2: Venn's diagram depicting the logical relations between RA, RAF, and F-generated sets and *organizations* under COT's definition. All RAF sets are organizations, but whether all organizations are F-generated is an ambiguous matter.

Figure 3: A: A chain of dependent catalyzations. B: A catalyzation loop

nizations, but the converse result (all organizations are F-generated sets) is more difficult to handle. We propose two different approaches: First, if one decides that the Food set corresponds only to the molecules generated from the empty set (in COTs phrasing of reactions), then it is clear that there are organizations which are not F-generated. On the other hand, for any organization it is always possible (due to the closure property) to find a suitable set (generally not unique)  $F$  such that the corresponding F-generated set is equal to the given organization. Thus, the extend to which organizations and F-generated sets overlap depends on which approach one takes to express COT systems in terms of RAF sets.

## The Loop Theorem

As most theories on biological organization are centered in the notion of closure (Letelier et al., 2011), RAF sets formalism give a succinct and useful description of closure. First, we shall consider a *chain* of catalyzations in which a product from one reaction catalyzes another reaction in the chain (figure 3A). If eventually a product catalyzes an earlier step (figure 3B), we have a catalyzation loop. As we shall see, in a RAO it is always possible to find such a catalyzation loop if the catalysts are not part of the food set. This condition seems natural for systems with metabolic closure.

Considering this definition we propose:

**Theorem 2** *If all catalysts in a RAO are generated by the system, then there is at least one catalyzation loop.*

**Proof:** In such a RAO every catalyst must be generated by a reaction, which in turn must be catalyzed too. In this sense, the production of every catalyst is directly dependent on another and indirectly dependent on a sequence of catalysts. The number of catalysts is finite therefore, at some point a catalyst must depend indirectly on itself, thus, forming at least one catalyzation loop. Note that not every catalyst is part of a loop as it is allowed that some catalysts may catalyze reactions which yield no catalysts as products, yet the system as a whole must have at least one catalyzation loop. Note that in case of direct autocatalysis, the loop is trivial. Also, whether there is more than one catalyzation loop is a question that must be addressed in each particular case.

An unsuspected consequence of the loop theorem is that some of the catalysts inside the catalyzation loop must have a dual catalytic role, that is enzymes that catalyze at least the creation of other two enzymes, if not happen the trivial case of all enzymes catalyze the creation of another one enzyme. This is interesting, as one modern re-interpretation of Rosen's results about how living systems avoid infinite regress is by having enzymes with dual functions (Letelier et al., 2006). Thus, this systemic result (i.e. existence of moonlighting enzymes) can be achieved by two different methods.

This theorem is a basic result that follows directly from the basic definitions of RAOs, but it shows an important property that needs to be underlined: the catalyzation loops (one or more) inside a RAO may be considered as its autocatalytic core and, functionally, there is a difference between the catalysts of the loop and the ones outside it.

We conjecture that the functional segregation hinted has important consequences. In effect, to confer stability to the core the catalysts outside it control the inflow and outflow of matter to and from the core. Thus, the net flow of matter inside it must be controlled, as a large flow would generate an exponential runaway and a small one would extinguish some core components, destroying its organization. Keeping this balance between in and outflow will be seen as homeostatic regulation. In summary, we conjecture that the catalyzation loop confers long term stability to the network. The analytical proof of this result seems difficult, but we did computer simulations in small (toy-like) systems and using mass-action kinetics, expresed for reactions:

By the formula:

$$\frac{d[p_k]}{dt} = k_1[c_1] \prod_i [s_i] - k_2[c_2] \prod_j [p_j]$$

Figure 4 shows one example for the temporal evolution of the concentrations of molecules for the RAF system of

Figure 4: Temporal evolution of RAF toy system (see figure 1). The system reaches a steady state in which all concentrations are different from 0.

Figure 5: Temporal evolution of a non-RAF system. Although the concentrations of the catalysts  $C_1$  and  $C_2$  were fixed, the system decays until its components disappear.

figure 1. We can see that a steady state is achieved. In figure 5 we simulated a similar system but without the reactions that generate or destroy the catalysts  $C_1$  or  $C_2$ , removing the catalyzation loop and making the system a non-RAF set. In this last case the concentrations of many components decay to zero, stopping the network dynamics.

We also did the bifurcation analysis by varying rate constants  $k_{in}$  and  $k_{out}$  corresponding to the reactions  $r_1 : \phi \rightarrow M$  and  $r_9 : W \rightarrow \phi$  respectively. For the RAF set, almost every combination of parameters  $k_{in}$  and  $k_{out}$  leads to a steady state, except at the border where  $k_{in} = 0$  or  $k_{out} = 0$  and some regions close to these.

On the other hand, the non-RAF set has no stable points for most values of  $k_{in}$  and  $k_{out}$ . This puts in evidence the relevance of the autocatalytic core, so that the growth of one part of the system encompasses the rest and grows harmonically and coherently between the inflow and outflow of matter.

## Growth and Homeostasis in Autopoietic Systems

Any increase in the concentration of a loop catalyst will translate into an increased concentration of every other cata-

Figure 6: Bifurcation diagram of the RAF set in figure 1, for variables  $k_{in}$  and  $k_{out}$ . A similar diagram for a non-RAF system has no stable region. (cyan dots=stable, black Xs=unstable).

lyst in the loop, which would consequently lead to a further increment of the first one, exhibiting an apparent autocatalytic behavior. At the same time, this loop must be connected to side branches that lead to the production of catalysts that are not directly related to autocatalysis, but with the obtention and processing of the food sources that sustain it. An interesting type of branches are the ones that lead to the regulation of the enzymes that control the in and outfluxes, because they are supposed to regulate the whole metabolisms growth rate by coordinating these fluxes. This fact shows us the importance of the topology, because every enzyme must be whether part of a loop or a branch of it, thus, a change in an enzyme concentration which is part of the loop will have repercussions in the whole systems growth, as it also affects the enzymes that regulate the fluxes. Thus, the RAF sets may help to understand the dynamics of the homeostatic process. This is not mutually exclusive with the fact that an increase in the concentration of an enzyme outside the loop may have a direct repercussion on global growth.

The loop theorem has an important application for autopoietic systems, that can be defined as self-encapsulated RAF sets. For an autopoietic system (that according to the above theorem must contain at least one autocatalytic loop) to be stable in time, there must be a fine balance between the generation and destruction of molecules. But there must also be a balance respective to control its volume in order to keep the concentrations unaltered. Thus, the organization (*à la* Autopoiesis) of a RAF set must be under a precise homeostatic control, as growth must be promoted, but in the context of compensating for the volume increase without suffering the consequences of autocatalytic growth. Thus, in a first

approach, we must allow for a system to grow in terms of the net amount of molecules, but not in concentration. This implies that volume must be under active control and that allowing the system to grow would not be a contradiction with homeostatic principles.

## Discussion and Conclusion

As we have previously stated (Jaramillo et al., 2010) we conclude again that RAF sets formalism is particularly suited to study closure. Of course many aspects of metabolic closure escape this theory (the operator of organizational invariance  $\beta$  of  $(M,R)$  systems is a prime example), but this framework provides a solid starting point. The loop theorem proved here, which is a property shared by RAOs, Autopoietic and  $(M,R)$  systems is a good example of its power.

Another important point of the present study is to apply the analysis of COT to RAF sets. As it is usual in theoretical biology, the different frameworks generated to explain living organization exist in closed universes without dialogue between competing theories. Here, we partially break this isolation by showing how organizations *à la* COT contain all RAF sets, but not all RA sets. This inclusion, although obvious and expected from a theoretical viewpoint, is not easy to prove. We have developed demonstrations using arguments from linear algebra, instead of the set theory arguments favored in RAF. The most unexpected result is the uncovering of chemical kinetics arguments in RAF sets. In effect, RAF sets appear to be a purely algebraic entity, without considerations for time nor kinetics; but as soon as their stoichiometric matrix is expressed, the kinetic arguments of COT are made obvious. Thus our lemmas and theorems show deep relations between the pure algebraic formulation of RAF sets with the dynamics of organizations in COT. Perhaps this same reasoning could be also be applied to  $(M,R)$  systems. Taken together, the results shown here show the value of putting all the different notions of metabolic closure under a common analytical umbrella.

COT has already produced an interesting number of results on the dynamics of reaction networks, in particular regarding to the long-term temporal behaviour and stability of these systems (Dittrich and Di Fenizio, 2007). An interesting result from this theory, which complements the loop theorem presented here, is the decomposition theorem for organizations (Veloz et al., 2011). This theorem states that, under certain conditions, it is possible to split a system into subsystems whose dynamic behaviour are weakly coupled. Thus, an open question is to investigate how our loop theorem, which seems to indicate that systems cannot be segmented, is compatible with such uncoupling of subsystems. In effect a catalyzation loop might constitute the minimum decomposable unit.

We presented the conjecture that systems with at least one catalyzation loop are more stable than similar systems without such loops. This is a powerful result that will unavoid-

ably demand tools from MCA, the most elaborate theory about fluxes in biochemical networks, to be proven or refuted.

In summary, our efforts show that closure is a conceptual key to understand biological organization, as an example we have come close to use closure as an argument to prove one theorem (loop theorem), which we believe is a valuable conceptual step and a fertile direction for theoretical biology.

## Abstract

Simple artificial agents representing more or less elaborated Braitenberg vehicles, usually adopt an egocentric view. One example is Walknet, a biologically inspired neural network controlling hexapod walking. Here we show how such a controller can be expanded to be able to interpret observed behaviours that are performed by other individuals, i.e. the system shows properties of a mirror system. This allows to further expand the network to become an “allocentric” system that might implement subjective feelings which could be attributed to other individuals, i.e. the system implements a Theory of Mind. As a last expansion we introduce a two-body model, or we-model, which may allow for mutualism. Application of we-models allows for what often has been called the third person’s view. The different steps proposed can be interpreted as corresponding to an evolutionary development.

## Introduction

Artificial agents being based on natural creatures may usually be characterized as to hold an ‘egocentric’ view: in such agents, the sensory input is related to the own body representing the center of the agent’s world. Correspondingly, motor output activities are based on the own geometrical—and possibly mental—position. Here we attempt to introduce a way how the controller of such an autonomous agent may be changed to allow the agent to ‘put itself into the partner’s shoes’, in other words to allow for theory of mind (ToM), and to show empathy. A further goal is to develop a (neuronal) control structure that may form the basis of mutualism, i.e. the faculty to cooperate with a partner using shared goals (Tomasello, 2009). Such a control structure may serve as a quantitatively defined hypothesis and may as such help to understand the underlying mechanisms of the corresponding biological system.

When attempting to simulate higher mental functions as are specific memory systems, attention, cognition or consciousness, for example, authors do, in general, not apply a whole-systems approach, but instead consider specific networks suited to represent the specific function of interest. Therefore, in many cases, it remains open how these specific networks may be embedded into the complete system, i.e. how the different networks are switched on or off and how these local networks receive input from and provide output for the complete system. To avoid this problem, we take a whole-systems approach. We investigate such phenomena under the

condition that these networks are embedded into an autonomously behaving agent, i.e. an agent equipped with a body characterised by many parallel and serially arranged degrees of freedom and a control network containing a set of preexisting reactive behaviours.

Schilling and Cruse (submitted) have proposed a network that has been worked out in more detail and called *reaCog* (this work is based on the reactive control system Walknet (Dürr et al., 2004) and the cognitive extensions have been introduced in Cruse and Schilling (2010)). This network is able to control a hexapod system by applying a structure consisting of two levels. The lower level is endowed with properties that correspond to insect-type behaviours (as are walking, climbing and navigation), about which already detailed knowledge is available (Dürr et al. 2004, Bläsing 2006, Wehner 2008). This level is based on a reactive, or behaviour-based, architecture, i.e. a collection of local, in general recurrent, neural networks (RNN). The second level of *reaCog* concerns an expansion allowing for the introduction of cognitive abilities as explained below. Generally, the architecture of our system is not based on the idea to consist of one holistic RNN, but represents a localist approach the advantages of which are convincingly advocated by Cooper and Shallice (2006).

When starting with an insect-like body and insect-inspired behaviour-based networks we do not imply that insects were endowed with higher cognitive functions as are metacognition, ToM or consciousness, although already in insects a number of astonishing properties can be found which by some authors are called cognitive (e.g. application of concepts like symmetry, sameness or protocounting, see Menzel et al., 2007). However, we assume that any cognitive system is strongly relying on such reactive—or behaviour-based—structures. Different to a reactive system, a cognitive system in the strict sense should be able to exploit stored information independent of the context in which this information has been acquired. This means, a cognitive system should be able to combine existing memory elements in a new way and use these new combinations for controlling behaviour and planning ahead. As we have shown by having developed *reaCog*, only a limited number of expansions are required to reach such a cognitive level (Cruse and Schilling 2010; Schilling and Cruse, submitted). The most important expansion concerns the introduction of a ‘manipulable’ body model. In order to be able to plan ahead, this internal model of

Fig. 1. An egocentric network represents the situation “Ego grasp candy”. The figure shows a section of the network reaCog (Schilling and Cruse, *subm.*). Local networks are symbolized by rectangles and names. Motivation units are shown by circles (connection to the corresponding network see Fig. 4). Active motivation units are marked by red colour. Arrows represent excitatory connections, T-shaped connections are inhibitory. Visual and proprioceptive input is marked by the half-circles, left side. Acoustic input representing words is shown by italic letters at the right side.

the own body (plus some aspects of the world, e.g. an obstacle) is required to internally simulate different behaviours in order to test whether this specific behaviour is suited to cope with an actual problem. The second expansion concerns an attention system. This system consists of two layers, a spreading activation layer (SAL) and a winner-take-all layer (WTA). This two-layer network enables the agent to select a specific behavioural element, which is normally not activated in the actual context. Via internal simulation, the system can then test whether this newly selected behavioural element is suited to solve the problem at hand, a procedure that has been termed “probehandeln” following Freud (1911). New behaviours found by this procedure and that, by means of the simulation and the subsequent behavioural test, prove to be adaptive will be stored in the long-term memory, thereby enriching the behaviour-based architecture. As for a well designed reactive system new problems may occur only rarely, reaCog can be regarded a reactive system that exploits its cognitive properties only for short periods of time required to solve a problem at hand.

Based on the ideas of Narayanan (Narayanan, 1997 and Feldman and Narayanan, 2004) and Steels (1995, 2003) we have further designed a simple expansion of reaCog that allows connecting behavioural elements of this system with so called word nets (RNNs representing an individual verbal expression, e.g. “leg”, or “swing”) that carry the corresponding meaning (Cruse, 2010). Therefore, the symbols are grounded (Steels, 2003) allowing the agent to ‘understand’ the meaning of such a word when given to the agent.

Like most other autonomous systems, reaCog holds an “egocentric” view. The agent might be able to recognize and represent objects. We further assume that the agent can also recognize, as a specific kind of object, a conspecific (see Steels and Spranger, 2008 and Spranger et al., 2009 for solutions). In addition we assume that the agent can attribute properties to the object or the partner (e.g. a face, a spatial position). All these expansions, however, do not enable the agent to “put himself into the partner’s shoes”. In other words,

the agent is not able to realize that the partner may see the agent himself as having a property (e.g. a position). Thus, in this network there is no possibility to represent the change of roles (“If I were him”). In other words, the capability to have a ToM is lacking. A classical procedure for testing whether an agent allows for the ability of ToM is the so called Sally-Anne task. Two subjects are shown that a candy lying on the table is hidden under a black cover. Then one subject, Sally, has to leave the room whilst the candy is now hidden under the white cover, as observed by Anne. After Sally has come back, Anne is asked under which cover Sally will probably search for the candy. If Anne points to the black cover, she is assumed to have ToM, but not, if she points to the white cover where the candy really is placed.

The network reaCog even less shows the ability to perform mutualistic behaviour (Tomasello, 2009), i.e. to develop shared goals and to try to follow them, even when the individual agent may receive no specific advantage. A simple example is when two individuals are trying to carry a load, for instance a table through an environment containing obstacles. In the reminder we show how reaCog can be expanded to endow the agent with these capabilities. To be in a position to explain the structures and their properties in an easily understandable way, we illustrate the expansions of reaCog by attempting to maintain the number of neuronal units as small as possible. In this way we hope to provide a functional understanding of how systems able to develop a ToM and later a structure allowing for mutualism may have arisen from an egocentric system. The different steps introduced might represent a hypothetical evolutionary sequence.

## The Model

To simplify the description, we will focus on a small section of reaCog as illustrated in Fig. 1. Basically, the network consists of sensorimotor networks, or memory elements, connected with motivation units. In the figures, the networks are indicated by rectangles with verbal descriptors. Motivation units (depicted as circles) can adopt an activation value within the interval  $[0,1]$ . In the figures, activated units are marked as red circles, inactive ones are shown as black circles. Two of these motivation units may either be connected via (mutual) inhibition or via (mutual) excitation, or not be connected at all. Groups of excitatorily connected units stabilize each other. I.e. when one unit of such a group is activated, all the members of that group will become activated, too, except for those units that are connected via mutual inhibition. These inhibitory connections form a local winner-take-all (WTA) net with the consequence that only one of these units will stay active over some iterations. Two such motivation units represent the state Awake and the state Sleep, respectively. In the awake state, several sensory or motor elements are activated. These elements may form different contextual groups. Here we focus on two such groups. One group refers to external objects, in this case a conspecific (“partner”), represented by the memory elements “face” and “position”, which stand for the visual appearance and spatial location of the partner to be recognized by the corresponding networks. Together with the unit Partner these motivation units form an excitatory network. The elements of the second group refer to the agent. The agent can select between a number of actions

(in Fig. 1 “push” and “grasp”), the motivation units of which are connected via mutual inhibition (connections with T-shaped endings). The agent is also assumed to recognize an object, a candy lying on the table. Fig. 1 shows a memory element representing the position of the candy (*pos.candy*) relative to the agent. The agent may also be equipped with a network representing the experience of pain, which is connected to any specific body position, but this faculty will only be explained later. The motivation unit connecting the agent-related elements has been called Ego unit in the figures. To avoid a possible misunderstanding, it should be made clear that this name represents only a technical term and should not be understood as to mean that the agent has any kind of self-knowledge. As mentioned, the system may also be equipped with word nets that allow to recognize verbal statements as “*grasp*” or “*candy*” or “*partner*” which, if stimulated, activate the corresponding sensorimotor networks (in the figures these inputs are indicated by the terms given in *italic*; the word nets themselves are not shown).

Of course, any partner, if being equipped with a corresponding network, may likewise recognize our agent, but, as mentioned, the agent does not know this.

The behaviour-based—or sensorimotor—RNNs indicated by rectangles in the figures might be realized as simple associators connecting a sensory input with a motor output (Dürr et al., 2004; Cruse and Wehner, 2011) and may function as an implicit body model, that can be used to control the behaviour by computing the inverse kinematics. Alternatively, as conceptualized in *reaCog* (Cruse and Schilling, 2010; Schilling, 2011; Schilling and Cruse, *subm.*), sensorimotor RNNs may be connected to an explicit body model. In this case, the network is equipped with a switch that allows to turn on or off the motor output to either control the behaviour or instead to activate only the body model and in this way simulate the behaviour. In the latter case, the system may be termed to imagine this behaviour.

To realize the motivation units and RNN units we use the so called Input Compensation (IC) units, type suppression units (Kühn et al. 2007, Makarov et al. 2008), first, because a simple learning algorithm is available to train such networks. Secondly, because such networks maintain the input activation as long as the input is provided, but, if trained to hold a static attractor, also after the input is switched off. A motivation unit that is connected to a behaviour-based RNN, controls the output of its network by multiplying the output by its activation value (see below, Fig. 5). In this way, a motivation unit when activated may be called to ‘open’ the corresponding network (representing a top-down influence). As will be mentioned below, sensorimotor networks may also be used to respond to sensory input. In this case, the network showing the best fit to the actual sensory input (or the smallest error) will activate its motivation unit (this bottom-up influence is not depicted in Fig. 5). In the simulation proposed here, only the motivation unit network has been studied (for an explicit simulation of such a network see Cruse and Wehner, 2011).

*Phenomenal aspect:* Before we continue to describe the property of the network in more detail, a fundamental, and unsolved problem has to be addressed. When trying to understand a cognitive system the question arises how a neuronal system representing a physical structure is able to

allow for the faculty to experience subjective feelings, an example is feeling pain. This subjective or phenomenal aspect is relevant for (at least some) living systems. What is the problem? We can easily think of neuronal structures that, activated by nociceptors, for example, may produce chemical substances or activate specific behaviours (e.g. withdrawal or speech acts), i.e. form a series of causally connected physical states. But there is no concrete idea how (and why) the fact that these (or some of these) physical activities are accompanied by the feeling of pain, i.e. the subjective aspect, may be reified. The problem of understanding the relation between the physical aspect and the phenomenal aspect has eventually been termed the ‘hard problem’ (Chalmers, 1996) and will not attempted to be solved here. In order to be nevertheless able to use terms describing (or at least associated with) subjective feelings when discussing the properties of our network, we make the following assumption. An RNN as used here can adopt attractor states that are reached when the network has been given enough time for relaxation. In mathematical terms the attractor state can be defined as the so-called harmony value of the net reaching a maximum value. Following Cruse (1999, 2003) we assume that the activation of such a network is accompanied by subjective experience (or a phenomenal aspect) if the harmony value of the net has reached a given threshold, in other words, if the net has sufficiently well approached its attractor state. This hypothesis does of course not represent a solution of the hard problem, but nonetheless provides a way to operationalise the problem. Its function in this context is to allow us using terms associated with subjective or phenomenal aspects when describing states of our physical network. Using this hypothesis we are in a position to bridge the ‘explanatory gap’ on a descriptive level. If other mechanisms underlying the phenomenal aspect were found, they could replace our hypothesis without, as we believe, influencing the rest of the arguments.

## The functioning of the network – an example

The agent equipped with *reaCog*, the, for our discussion, relevant part of which is depicted in Fig. 1, is able to show the following simple behaviour. If we assume that elements “*grasp*” and “*pos.candy*” are activated by an external verbal command as indicated by thin arrows (in the figures marked by *italic* letters, e.g. Fig. 1 *grasp*, *candy*), this input will activate the motivation units *grasp* and *pos.candy*. The former will open the behaviour represented in the RNN *grasp* and activate the unit Ego. Further, the unit *pos.candy* when activated will open the RNN allowing to recognize the spatial position of the candy. The *grasp* network receives input from the *pos.candy* network that provides the information to the *grasp* network concerning the goal for the movement to be performed. Therefore, the movement can now be executed. As an alternative to verbally given input, the agent, after having registered the candy, may decide to perform a grasp movement, the decision being determined by its internal state requiring a network not shown in the figures. In the following examples we will however use verbal input only, because this simplifies explanation of the concepts proposed. As illustrated in Fig. 1, at the same time the agent may be able to represent a partner, characterized by its face and its position.

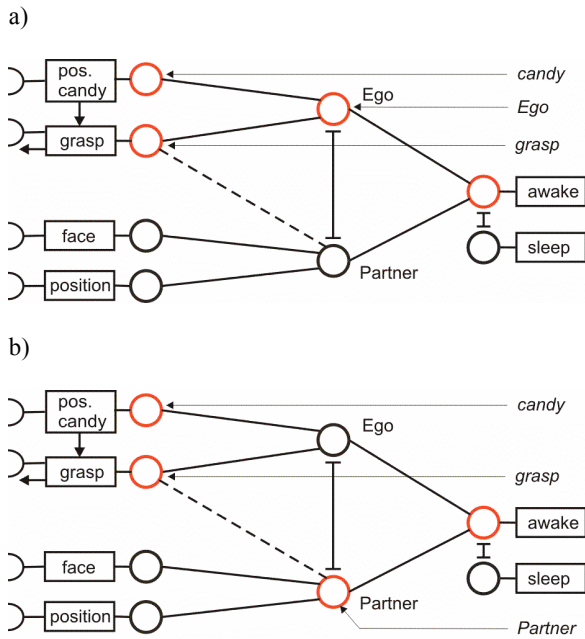

Fig. 2. An egocentric network representing the situation “Ego grasp candy” (a) and the situation “Partner is seen as grasping a candy” (b). The sensorimotor element “grasp” provides motor output and receives sensory (e.g. visual) input. Its units show properties corresponding to those of mirror neurons as it represents a circuit shared between the Ego and the partner units. See Fig. 1 for further explanation.

## Mirror systems

How may this network be changed to allow for ToM and mutualism? Several changes are proposed as will be illustrated in consecutive steps depicted in Figs. 2, 3 and 4.

A body model, apart from being used to control movement by calculating the inverse kinematics (Fig. 1), can also be used for a different purpose. When observing somebody else performing a grasp or a push movement, the visual input can be given to the body model which then can be used to simulate, or “internally copy”, the observed behaviour (e.g. “grasp”) following the “simulation theory” (e.g. Jeannerod, 2006 & 1999, Gallese & Lakoff, 2005). This application of the body model is suited to minimize errors when interpreting the (underspecified) visual input (e.g. Schilling, 2011). To symbolize this ability, in Fig. 2 the net ‘grasp’ is also equipped with sensory (visual) input. By application of a specific RNN forming a holistic system as has been proposed by Cruse and Schilling (2010) and Schilling (2011), one and the same body model is exploited for both purposes as are motor control and interpretation of sensory input. If a grasping movement is observed, the body model activates the element ‘grasp’. To allow the representation of the partner performing a grasping movement, too, we need another expansion, namely the introduction of connections between the unit representing the partner with (some of) the behavioural elements that, in the egocentric system (Fig. 1), are only

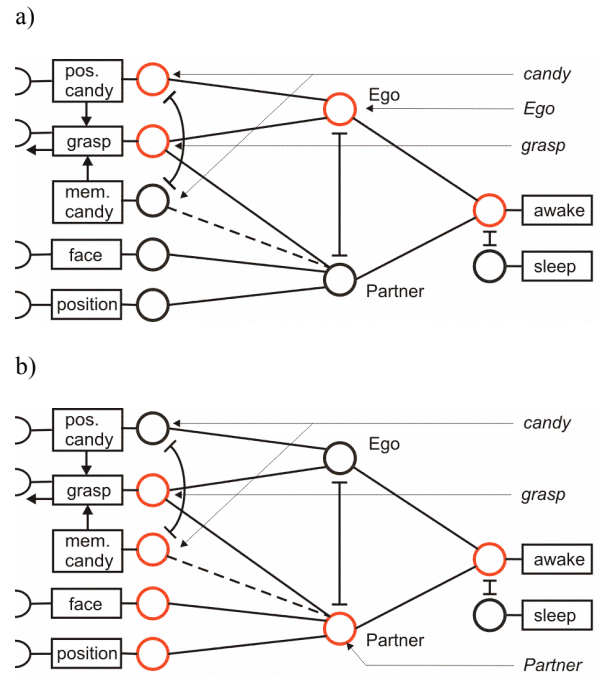

Fig. 3. A network being able to represent an egocentric view (a, situation “Ego grasp candy”) and the view as seen by the partner (b, situation “Partner grasp candy”), thus allowing for ToM. For further explanations see Fig. 1 and text.

connected with the Ego Unit. In our example this refers to element ‘grasp’ (see Fig. 2, dashed line). In addition, Unit Ego and unit Partner have to be connected via mutual inhibition (Fig. 2). This means that either unit Ego or unit Partner can be activated at a given moment in time.

With this network we can represent two situations: (i) if, as depicted in Fig. 2a, units Ego, grasp and pos.candy are coactivated, the network represents the agent to grasp the candy or to imagine such a grasping movement (the representation of this situation is already possible for the network shown in Fig. 1). (ii) However, the agent can also record a grasping movement of the partner. In this case, the sensorimotor element ‘grasp’ is activated together with the unit Partner, whereas unit Ego is inhibited. In Fig. 2b this situation is illustrated by motivation unit Partner shown in red and unit Ego in black. In both situations the neurons of the element grasp are activated. Such an architecture has eventually be termed to apply ‘shared circuits’ and strongly reminds of properties characterizing mirror neurons. Therefore, application of such shared circuits has been described as ‘mirroring’ (Keyers and Gazzola, 2011). Units of the grasp net represent to movement and its goal, and thus correspond to represent a motor act as attributed to mirror neurons (Rizzolatti and Luppino 2001). However, the goal in both cases (Fig. 2a, 2b) is represented as being viewed by the agent, not as being represented by the partner.

## Theory of Mind

Therefore, both circuits, as depicted in Fig. 1 and Fig. 2a,b still represent egocentric systems. We will now proceed allowing the agent to be able to simulate the behaviour and the internal view, including the sensory experience, of the partner, a property that has been characterized as ToM. To this end, we will present a simple simulation of the Sally-Anne task mentioned above. To be able to represent some aspects of the memory of the partner required for this task, in our network the unit **Partner** is given a connection to memory elements representing the position of the candy as viewed by the partner (Fig. 3, dashed line). Now imagine that subject Anne is either equipped with a network as depicted in Fig. 2 or in Fig. 3. Application of a system shown in Fig. 2 means that the agent (Anne) has only one representation of the candy's position, the one seen last. Therefore only this, correct, position can be activated and the partner is imagined to grasp the correct position as observed in children younger than about four years. The child is not taking into account the position the partner assumes. In contrast in a system as presented in Fig. 3a, there is a difference in thinking of oneself grasping the candy or the partner doing it. When the agent imagines itself to grasp the candy, it would grasp to the correct and known position. If asked to simulate the internal state of the partner, as is required in the case of the Sally-Anne test, (Fig. 3b), the position connected to the partner Sally will be used and the agent would rightfully deduct that the partners grasp would be directed towards this position which is wrong, but this fact is not known by the partner. Therefore, the network shown in Fig. 3 allows for ToM, in contrast to the network shown in Fig. 2. The critical difference between both networks is that the network shown in Fig. 3 contains a separate representation of (a part of) the partner's memory. Ishida et al. (2010) describe mirror neurons that are able to represent this property.

## Feeling pain

To illustrate another, more difficult case, let us come back to a push movement being directed to a partner. This case is more complex because roles can be interchanged in this scenario as the partner could also push the agent. To simulate this situation, the Ego network has correspondingly to be equipped with an element containing its spatial position, called "pos.Ego" in Fig. 4 (to simplify the figure, elements "grasp" and pos.candy are omitted in this and the later figures). In the following, two possible situations are considered, (1) the agent pushing the partner ("Ego push Partner") and (2) the partner pushing the agent ("Partner push Ego"). In these situations the agent may act as an actor (corresponding to a grammatical subject in an active phrase) or as a patient (corresponding to a grammatical object in an active phrase). Therefore, instead of having one unit for each individual as in the networks explained above, we introduce now two units to represent each individual, the agent and the partner. The corresponding subject units and object units are arranged under the column "subject" and "object" (Fig. 4a,b) and are connected via mutual inhibition.

To represent a verbally given situation like "Ego push Partner" in the network, some way is required to define roles. Here we assume that the item given first in time functions as

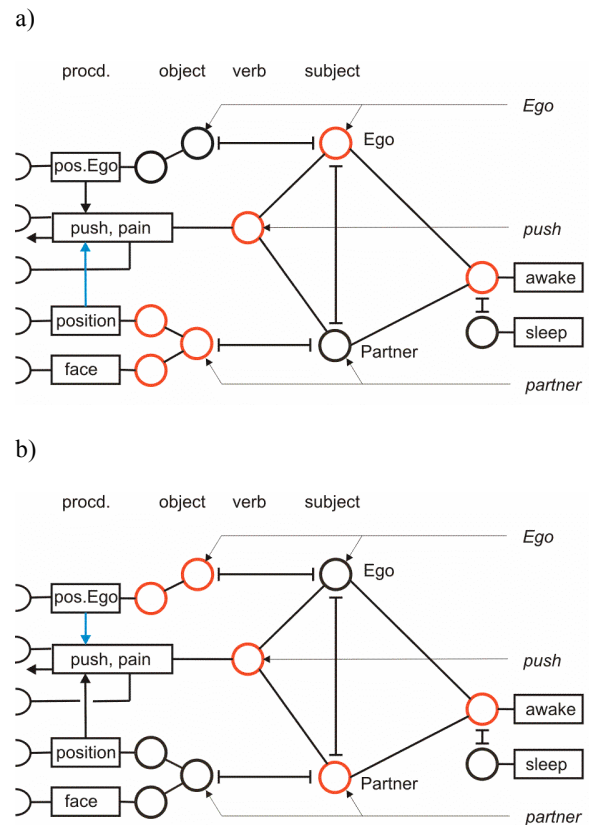

Fig. 4. A network allowing for ToM, being able to represent an egocentric view (a, situation "Ego push Partner") and the view as seen by the partner (b, situation "Partner push Ego"). Units for individuals (agent, partner) can be represented by an 'object unit' or a 'subject unit', as indicated in the top line. Sensorimotor, or procedural, networks can be found under the heading 'procd.', action units under 'verb'. For further explanation see Fig. 1 and text.

subject, the second as verb, and the third as object. The network shown in Fig. 4a,b maps the temporal order into the neuronal structure. Beginning with situation (1) input *Ego* is given first and is immediately followed by *push*. This leads to an activation of the unit Push and the Ego-subject unit (Fig. 4a, red) and an inhibition of both the Ego-object unit and the Partner-subject unit. Ego-subject unit is activated rather than the Ego-object unit because only the former is supported by activation of the unit Push. Later, both partner units will be activated via input "*partner*". As the Partner-subject unit is already inhibited, the Partner-object unit will win, in turn activating its position unit (Fig. 4a, red). Thus, all units required to represent situation (1)—the agent performs a push directed to the partner position—are active. In this way, this network can represent the egocentric view as was already possible for the networks shown in Figs. 1 and 2.<sup>1</sup>

<sup>1</sup> If the situation is not given by verbal input, but for example by visual observation, the roles of the different items actor, action and patient may

Fig. 5. A recurrent network using five IC units that shows in more detail the sensorimotor element termed “push, pain” in Fig. 5. The uppermost three units represent a simple (one-dimensional) form of the push controller (vel: velocity of the end-effector, x: position of the end-effector, also used as motor output, diff: spatial difference between actual position and goal position, the latter represented by unit “pos”). The recurrent network “pain”, consisting of one unit, when activated long enough represents the neuronal substrate for feeling pain. The unit diff possess a nonlinear activation function that allows to activate the pain network when the activation of the unit diff has approached a value of about zero. The activation of the complete network is controlled by a motivation unit (red circle).

The same network can however correspondingly represent situation (2) “Partner push Ego”. To this end, the partner units, now representing the actor, are first activated together with Push, whereas in a later step unit Ego is activated. In a corresponding way, at the end Partner-subject unit, unit Push, as well as Ego-object unit and Ego-position unit remain active (Fig. 4b).

If the agent is confronted with the latter situation “Partner push Ego” for the first time, it may suffer from a painful feeling, which will then be associated with being pushed. The network whose activation is accompanied by the subjective experience of pain (Fig. 4, box ‘push,pain’), is integrated into the push network in the following way. The pain network is activated when the controlled position of the tip of the arm reaches the goal position, the pain being associated with the goal position.

To illustrate how the networks push and pain and the input from the position network are connected, in Fig. 5 a minimal version of this subnetwork is depicted in more detail. The network altogether consists of five IC units plus one motivation unit. The push network contains three units, one representing position of the end-effector of the arm characterized by one dimension, x, the (constant) velocity of the end-effector, vel, and a unit diff representing the difference between the actual position x and the target position pos. Unit diff has a nonlinear activation function

be internally represented by different salience values provided by neuronal systems able to detect these different roles.

providing an output of 1 in a small interval around an activation value of zero, and providing a zero output otherwise. In all three cases, one unit suffices to represent the corresponding values as we focus on a one-dimensional example.<sup>2</sup> Furthermore, there is an RNN, consisting of one unit that when activated represents a painful state (pain). Unit pain is activated as soon as the end-effector meets the target position (diff = 0). We will not deal with the question how these weights are learned.

If—after this network has been installed and the situation (1) “Ego push Partner” is activated (either as active behaviour or only as imagined, i.e. simulated, behaviour)—the position of the partner will be associated with the feeling of pain (arrow highlighted in blue in Fig. 4a). In this way, our agent can simulate and thereby experience the experience of the partner without confusion between the two individuals. This means that the agent shows the ability being endowed with empathy (following the definition of Decety and Jackson, 2004: “Empathy accounts for the [...] subjective experience of similarity between the feelings expressed by self and others without losing sight of whose feelings belong to whom”). Coming back again to the second situation (Fig. 4b), “Partner push Ego”, the agent can simulate the view of the partner being an actor. Now the position of the agent is provided to the push network (in Fig. 4b depicted by a blue arrow). Therefore the network of the agent can simulate that the agent himself is receiving a push and experiencing a painful feeling. Thus, the simulated partner can now be experienced as to experience the pain.

Taken together, the agent equipped with a network as shown in Figs. 3, 4 can experience an egocentric view as was already possible for the networks shown in Fig. 1 or 2 (see Figs. 3a and 4a). In addition, the agent is able to ‘put himself into the shoes of the partner’ in two ways: the agent can try to understand the view of its partner onto objects (Fig. 3) or onto itself (Fig. 3b and 4b), i.e. “seeing himself with the eyes of the conspecific” (ToM), and can experience the experience of the partner (Fig. 4a) by simulating the feeling of the partner. The simulation of the partner is of course based on the innate and learned structures underlying his own ability to feel.

## Mutualism

A further evolutionary as well as developmental step that, according to Tomasello (2009) is unique for humans, is described by the term mutualism. Mutualism concerns the property of an agent to cooperate with another agent in such a way that both individuals perform—possibly different—actions by which a common goal should be reached and where both individuals will profit. A simple case is to carry a heavy load (e.g. to move a table around obstacles). A formally related task has to be solved by a hexapod walker where the legs are considered to be driven by independent controllers, but the legs being mechanically coupled via the body and the ground. For this problem two different solutions have been proposed. One solution possibly realized by insects exploits the mechanical coupling of the legs applying an extremely

<sup>2</sup> Note that we reduce these networks to a minimum size in order to better explain the essential aspects. Of course, each network could be expanded to consist of a large number of units without touching the basic statements made here.

Fig. 6. A network allowing for the control of mutualistic behaviour. If input “shared intention” is activated, the (excitatory and inhibitory) connections between the subnetworks representing the agent (Ego) and the partner are interrupted. Therefore, both subnetworks can be used simultaneously to simulate actions that pursue a common goal. For further explanations see text and Fig. 1.

decentralized control structure (Schmitz et al., 2008). As an in our context more interesting alternative, Cruse and Schilling (2010) and Schilling (2011) proposed the application of an internal model that allows to simulate the legs plus their mechanical coupling through the world. Using this model each leg controller provides commands to its leg in such a way that each individual leg supports the common goal, namely moving the body forward. Applying this example to our problem of considering two independent agents able to behave mutualistically, the controller of each agent should correspondingly possess a model not only of itself, but also of the partner and the relevant environmental conditions. Together, these three elements form a ‘supermodel’. In analogy to Tomasello’s terminology, this model might also be called a “we-model”. Application of this supermodel can correspondingly be used for *probehandeln*, i.e. imagined behaviour, in order to reach a common goal. Indeed, Tomasello argued that the ability to have a we-mode is a prerequisite for developing a common goal.

What are the requirements for such a we-model to be implemented? First, the ability has to be given that actions of both the agent and the partner can be simulated independently and simultaneously. This means that it does not suffice to have only one body model that can be used to either simulate the Ego or the partner as was the case for the ‘shared-circuits’ networks shown above (Figs. 2, 3, 4). Rather, both motivation units, Ego and Partner, require access to separate behavioural elements (e.g. push) and a body model each. In Fig. 6, as in Figs. 2, 3, 4, the body model is not shown explicitly, but is graphically embedded in the push network. Both body models have to be connected via a model simulating (part of) the world to represent the actual situation, in our example the table to be carried. Furthermore, to activate the we-model, the mutual inhibition between both motivation units Ego and Partner has to be suppressed (Fig. 6). A suppression is also necessary for the connection between the motivation unit Partner and the push model which in the networks shown in Figs. 3, 4 is necessary because the latter is shared between the

Ego and the Partner network. Therefore, the we-model is activated by an input termed shared intention in Fig. 6. Tomasello has already considered shared intention a crucial property for a system showing mutualism. If this mode has been adopted, the we-model can be used to search for a solution to a given problem, for example moving the table. This search, of course, takes into account actual sensory information, e.g. position of the table relative to both individuals, movement of the other individual and possibly verbal information.

## Discussion

In our earlier work, we proposed a network that is able to control behaviour (walking, climbing, navigation) using a behaviour-based architecture and that has been expanded to show a fundamental cognitive ability, namely to be able to plan ahead. Here we propose several expansions of this network, *reaCog*. As these expansions follow the basic structure of *reaCog*, they can easily be implemented in the *reaCog* architecture. Using a typical section of *reaCog*, as an example, we start with an egocentric system (Fig. 1) that contains a body model, but is not able of mirroring. In the first step, we introduce a new connection that allows the egocentric system to apply a mirror system, i.e. to interpret behaviours observed when being performed by other individuals (Fig. 2). However, application of shared circuits alone does not appear sufficient to allow for the representation of how the world is represented by others, i.e., to allow the network shown in Fig. 2 to solve the Sally-Anne task. The latter is however possible for the networks developed in the next step (Figs. 3 and 4), which in addition contain a representation of parts of the partner’s memory. The latter concerns the position of an object, the candy in the example shown in Fig. 3 or the position of the partner (Fig. 4). In the latter example, (Figs. 4, 5), we explain in more detail how this system might implement subjective feelings which could be attributed to other individuals. Both networks are able to apply ToM. The architecture shown in Fig. 4 is still based on the application of shared circuits as the push/pain network can be connected to either the unit Ego or the unit Partner. Separation into subject units and object units is required to represent the different roles the agents have to play in this paradigm. In contrast to the egocentric systems (Figs. 1, 2), the systems depicted in Figs. 3 and 4 may be called allocentric.

Fig. 6 shows what additional connections may be required to allow for mutualism. Here two body models can be activated simultaneously and the connections allowing for sharing circuits are inhibited. Application of such a we-model is suited to allow for what often has been called the third person’s view. The step from a network as shown in Fig. 4 to that presented in Fig. 6 appears to correspond to an idea proposed by Keyers and Gazzola (2011) who draw a distinction between application of shared circuits, used for mirroring to understand the partner at a lower, intuitive, non-cognitive level, and another system involving different brain areas when subjects are asked to reflect on others. According to Keyers and Gazzola, both mechanisms are activated according to the abstraction level of the actual task. Such a two-body model appears also to be helpful to explain a number of experimental results reviewed by Sebanz et al.

(2006) and Vesper et al. (2010) which show that subjects require shared representations of tasks including the simulation of the expected behaviour of confederates.

It might be tempting to speculate that the existence of these two body models might form the basis of some illusory own-body perceptions where, due to specific neuronal deficits, subjects can experience two body representations and self-identification refers either to the physical body (Autoscopy), to the illusory body (Out-of-Body experiences) or to both either simultaneously or in alternation (Heautoscopy) as described by Blanke and Metzinger (2009). In our system such illusions may result if accidentally both body models are connected to the unit Ego, a connection not depicted in Fig. 6.

## Abstract

This paper explores temporal and spatial dynamics of a population of Genetic Regulatory Networks (GRN). In order to so, a GRN model is spatially distributed to solve a multi-cellular Artificial Embryogeny problem, and Evolutionary Computation is used to optimize the developmental sequences. An in-depth analysis is provided and show that such a population of GRN display strong spatial synchronization as well as various kind of behavioral patterns, ranging from smooth diffusion to abrupt transition patterns.

## Introduction

Widely studied in Biology, Gene Regulatory Networks (GRN) have drawn in recent years a growing attention from the field of Artificial Life and Evolutionary Computation. Indeed, GRN are known to display rich dynamics and have been both experimentally studied through simplified models (Jakobi, 1995; Banzhaf, 2003) as well as applied to control optimization problems such as the well-known inverted pole balancing problem (Nicolau et al., 2010) and foraging agents (Joachimczak and Wróbel, 2010). In these recent works, evolving artificial GRN have always been shown to be competitive with the state-of-the-art neuro-evolution techniques, possibly because of rich internal dynamics. However, while temporal dynamics within a single GRN have already been studied Banzhaf (2003), the spatial dynamics resulting from coupling of several GRNs remains to be explored.

The core motivation in this paper is to describe and study such temporal *and* spatial dynamics of a population of GRN in the context of a spatial computation problem. The methodology followed relies on Evolutionary Computation to provide optimization tools so as to fine tune the GRN parameters and structure for solving a typical multi-cellular artificial embryogeny problem. In this setup, the GRNs act as a decision model that is spatially distributed over a set of *cells* that interact on a local basis such that the whole *organism* converges towards a global state that is the closest possible to a pre-defined target state (e.g. a particular pattern).

Rather than performance on target matching, we study the emerging spatial and temporal dynamics during the course

of the developmental process from the initial state to the end of development. Experimental investigations show that gene expressions are indeed strongly synchronized among GRNs, and display several behavioral patterns from smooth diffusion to abrupt transitions.

In the following, a review of existing artificial GRN models is provided. Then, the GRN model originally proposed by Banzhaf (2003) is introduced as well as the developmental model used in this study. The combination of both models is described, and experimental investigations are conducted on the spatial and temporal dynamics of GRN. The paper concludes with a discussion and sketches future directions.

## Background on artificial regulatory networks

Many current developmental models rely on an Artificial GRN to simulate cell differentiation. These systems are more or less inspired by gene regulation systems of living systems. In living systems, organisms' cells have several functions. They are described in the organism genome and their expressions are controlled by the regulatory network (Davidson, 2006). Cells use external signals from their environment to activate or inhibit the transcription of genes into mRNA (messenger RiboNucleic Acid), the copy of the daughter cell's DNA (DeoxyriboNucleic Acid). Cells collect external signals through protein sensors localized on the cell membrane. Then, gene expression within a cell determines its behavior.

Eggenberger (1997) was one of the first to use a regulatory network to generate a 3-D organisms able to move in its environment by modifying its morphology. Reil (1999) proposed a biologically plausible model, with a genome defined as a vector of numbers. In this model, each gene starts with a particular sequence (0101), named the "promoter". Then, a graph visualisation is used to observe gene activations and inhibitions over time with randomly generated networks. Observations revealed the existence of several patterns such as gene activation sequencing, chaotic expressions or cyclic expressions. The author also pointed out that the system was able to display pattern self-repairing after random genome deteriorations. Banzhaf (2003) also described an artificial

GRN model strongly inspired by real-world gene regulation. This model will be detailed in the next section.

Starting from these two seminal models, various extensions and variations have been explored, for addressing various concerns and applications. Several works addressed Artificial Embryogeny problems with models of GRN ranging from cellular automaton modeling (Chavoya and Duthen, 2008) to stripped-down version of GRN combined with complex developmental systems (Knabe et al., 2008; Joachimczak and Wróbel, 2008; Doursat, 2008). Some works have also addressed control problems: using GRN as a control function to map a virtual robot's sensory inputs to its motor actuator values. This has been applied in various setup, from foraging agents (Joachimczak and Wróbel, 2010) to pole balancing (Nicolau et al., 2010).

Few case studies have been done to explain how regulatory networks can solve these problems. Schramm et al. (2010) studies the impact of the evolutionary process on the network itself. Other papers of the literature such as Mjølness et al. (1991) or Thomas et al. (1995) propose an analysis of the regulatory network dynamics in a biological point of view. However, few papers deal with the analysis of such dynamics on artificial regulatory networks, which could be useful if we want to use effectively the computational abilities of these models. The aim of this paper is to show the gene expression temporal answer of a regulatory network to solve a spatial problem. For this purpose, we use Banzhaf's GRN (Banzhaf, 2003) and its extension to a computational model presented in (Nicolau et al., 2010). The next section describes this model.

## The gene regulatory network

### The model

In this work, we consider the artificial Gene Regulatory Network (GRN) introduced by Banzhaf (2003). In this model, the network is coded into the genome as a sequence of 32-bit strings (termed *sites*). Each gene in the genome is marked by a particular sequence named the "promoter". When a promoter is detected, the next five sites represent a gene sequence that codes for a protein to be produced. Each site codes for a different molecule of the protein. The concentration of this protein will determine the expression level of the corresponding gene.

To determine the protein's concentration and thus the gene expression level, two sites, coded upstream of the promoter, enhance and inhibit the protein production. The dynamics of enhancer signal  $e_i$  and inhibitor signal  $h_i$  of a protein  $i$  are given by the following equations:

$$e_i = \frac{1}{N} \sum_{j=1}^N c_j \exp^{\beta(u_j^+ - u_{max}^+)} \quad (1)$$

$$h_i = \frac{1}{N} \sum_{j=1}^N c_j \exp^{\beta(u_j^- - u_{max}^-)} \quad (2)$$

where  $N$  is the total number of proteins,  $c_j$  is the concentration of the protein  $j$ ,  $\beta$  is a scaling factor,  $u_j^+$  (resp.  $u_j^-$ ) is the matching degree of the enhancer (resp. inhibitor) site with the protein  $j$  and  $u_{max}^+$  (resp.  $u_{max}^-$ ) is maximum enhancer's (resp. inhibitor's) matching degree observed in the whole genome. The matching degree  $u_j^+$  (resp.  $u_j^-$ ) consists in counting the number of "1" resulting from the application of a XOR operation to the protein  $j$  and the enhancer (resp. inhibitor) pattern. The exponential function increases the impact of high value of gene expression and filter low values.

Finally, the concentration of produced protein  $p_i$  follows the differential equation  $dc_i/dt = \delta(e_i - h_i)c_i - \Phi(1.0)$ , where  $\delta$  is a scaling factor and  $\Phi(1.0)$  constrains the sum of all concentration equals to 1.0.

### Extension to a computational model

Originally, Banzhaf's artificial GRN is limited to study internal network dynamics. In order to use this model as a control function, Nicolau et al. (2010) proposed an extension by adding inputs and outputs to the regulatory network. This extension is detailed in the following.

**Inputs** Input values are coded with integers that will correspond to existing proteins. These input proteins can be involved in the regulatory process in two different ways: with their signatures to be considered during the matching process (in equations of  $e_i$  and  $h_i$ ) or with their input value to modify the differential equation  $dc_i/dt$  of protein concentrations. Here, the second solution has been chosen as it allows a better resolution with regard to a continuous domain of the problem addressed in this paper.

**Outputs** In order to produce outputs in the regulatory networks, genes are separated into classes: transcription factors *TF-genes* and product proteins *P-genes*. Whereas TF-genes play the roles of regulatory proteins as in the original Banzhaf's model, P-genes are only regulated but do not regulate other proteins: their expression levels provide the desired output signals. These two kinds of genes are identified by introducing two new promoters, whose signatures are chosen so that their probability of occurrence is equivalent and their matching as low as possible.

In the following, the regulatory network is used to produce cell differentiation, expressed by a cell coloration, while the developmental model described in the next section is responsible for the generation of the shape.

### The developmental model

The Generative Developmental System (GDS) *Cell2Organ* is composed of three layers of simulation: a *chemical* layer,

a *hydrodynamic* layer and a *physical* layer. These three layers can be enabled or disabled according to the needs of the experimentation. In the scope of this work, only the chemical layer is considered and will be described. More details about the developmental model are given in (Cussat-Blanc et al., 2008, 2010b,a).

The environment, implemented as a 2-D toroidal grid, contains several kinds of substrates. They spread within the grid, minimizing the variation of substrate quantities between two neighboring points. These substrates can spread on the grid at different speeds. Substrates can interact together in order to simulate a simplified chemical reaction. Only cells can trigger substrate transformations and collect or consume the energy of the transformation.

Cells act in the environment. Each cell contains sensors and has different abilities (or actions). An action has a energetic cost for the cell that will trigger it. An action selection system allows the cell to select the best action to perform at any moment of the simulation. This system is based on a set of rules *precondition*→*action* (*priority*). It uses data given by sensors to select the best action to perform.

*Division* is a particular action that can be performed if three conditions are respected. First, the cell must have at least one free neighbor to create the new cell. Secondly, the cell must have enough vital energy to perform the division (this required level is defined *a priori*). Finally, during the environment modeling, additional conditions can be added. A new cell created after division is totally independent and interacts with the environment. During the division, the GRN is executed in order to determinate the cell's color according to the morphogen quantity observed by the cell.

This model has been applied to shape generation (assembly of cells) in (Cussat-Blanc et al., 2008): a simple control function is evolutionary optimized to control cells so that it is possible to produce target shapes at the level of the organism within an environment with pre-positioned morphogens. In the current work, the control function considered is the extended Banzhaf's GRN model, coupled with an Evolution Strategies optimizer. Coupling the two models (GRN and developmental) is described in the next section.

## Coupling of the GRN and the GDS

### Precomputation of the cell differentiation

Different morphogen gradients are added to position cells in the environment. These morphogens are dedicated to differentiation. The configuration of these gradients will be described precisely for each experiment.

The cell differentiation is represented in the developmental model by a cell coloration. The concentration in morphogens measured by the cell in the environment defines the inputs of the regulatory network. These concentration are scaled to the range  $[0.0, 0.3]$  in order not to overload the production of other regulatory proteins (the sum of all concentrations is normalized in the range  $[0.0, 1.0]$ ). To obtain

the cell coloration, each cell executes the regulatory network during its division stage. Only one color can be expressed. Therefore, the maximum of the expression level of all genes is taken after a stabilization of the network (chosen empirically after 1000 time steps of the regulatory network evolution). This gene expression will finally give the cell color during the development of the organism.

Because the cell can be positioned in a coordinate system and the morphogen gradients are prepositioned, the differentiation mechanism can be precomputed before the development stage. In other words, the problem can be translated to the search of an integer matrix. Each value of the matrix corresponds to the color of the corresponding cell in the chemical environment (1 for white, 2 for red and 3 for blue). The same regulatory network is independently executed at each point of the matrix with the morphogen concentrations that corresponds in the chemical environment. The regulatory network is used to generate a differentiation matrix that correspond to the desired pattern (also translated to an integer matrix). The developmental model then determines cell coloration using this differentiation matrix during the organism growth. During temporal development, this matrix thus simplifies computation within the model as cell differentiation can be directly set at cell creation. This is justified in the present context as pre-computing morphogen diffusion is a sub-problem that may not be critical for studying the already rich GRN dynamics.

### Evolutionary algorithm

A classical (250+250) evolution strategy (ES) evolves a population of regulatory networks coded by the binary string previously presented. The (250+250) evolution strategy consists in producing 250 offsprings from 250 parents and choosing the 250 best genomes to form the next population. The fitness function that evaluates each genome consists of counting the number of cells that do not match the desire pattern (wrong cell coloration). The evolution strategy is launched for 100 generation to minimize the quadratic error. In the following, the error is computed as the difference for each pixels between the image generated by the organism (cell differentiation determines pixel color) and the target image.

Genome modifications are only regulated by a common bit-flip mutation operator. The mutation rate is set to 2% at the beginning of the run and adapted by the 1/5 rule of evolution strategies (Rechenberg, 1994): (1) the mutation rate is doubled when the rate of successful mutation is higher than 20%; (2) the mutation rate is divided by two when the rate of successful mutation is lower than 20%; (3) the mutation rate is doubled when the number of gene mutations in the population is less than 250 by generation.

The regulatory network's genome is randomly initialized. It is then duplicated 9 times with a mutation rate of 2% in order to increase the appearance probability of reg-

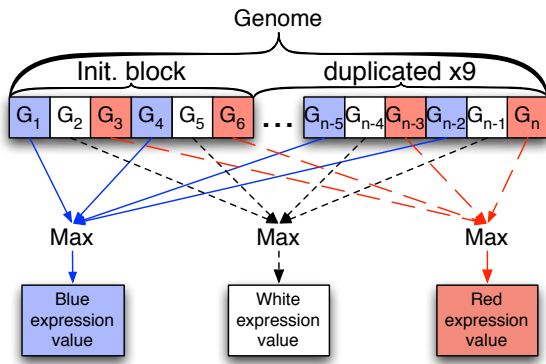

Figure 1: The genes of the genome are classified into three sub-parts: blue, white and red genes. The final expression value of each color is given by the highest value of the corresponding genes.

ulation sites. However, only three genes are necessary to code the three needed colors (blue, white and red cell colors). The duplication of the genome implies a strong possibility to have more than the three needed genes coded in the genome. As described on figure 1, the genome is divided in three sub-part. Each part codes for a specific color: blue, white and red. The highest gene expression value in one of the three sub-parts of the genome is taken as the expression value of the corresponding color.

Each differentiation matrix is developed only one time because the problem is deterministic. In other words, a regulatory network will always generate the same differentiation matrix and thus the same cellular pattern.

Figure 2 presents the convergence curves of the evolution strategy applied to our two problems of flag development presented in the next section. We can observe a stepwise evolution due to the only use of mutation. Moreover, even if the algorithm is set for 100 generations, it converges much faster (approx. 30 generations).

Figure 2: Convergence of the ES applied to a 45 cells French flag (left) and a 213 cell Japanese flag (right). X-axis represents the generation and the ordinate the min, mean and max fitness values (number of errors) for each generation.

## Experiments

### Benchmark: the French flag problem

In recent years, the French flag problem has become a classical benchmark for evolutionary computation. Introduced by Wolpert at the end of the 1960s (Wolpert, 1968), it consists in developing a French flag pattern starting from a single cell in the centre. This pattern is composed of three colored strips (blue, white and red). The French flag problem has various point of interests. In this paper, it is relevant as a spatial problem as it can highlight the differentiation capacities of a GRN-controlled developmental model: the color changes in the flag can easily be interpreted as a functional switch of the cell.

This benchmark has been addressed using various approaches. Lindenmayer (1971) used it to point out the capacity of his L-Systems to generate predefined shapes. Miller (2003) used a cartesian genetic programming approach and addressed self-repairing issues. Bowers (2005) used an embryonic developmental model to produce a French flag. (Devert, 2009) addressed this problem with various methods based on using the NEAT neuro-evolution method (Stanley, 2004), Jaeger's Echo State Networks (Jaeger, 2001) and a reaction-diffusion model bearing resemblance with the original Miller's model.

This benchmark became quite famous in the Artificial GRN community as it can be used to show gene expressions of cells (Banzhaf, 2003; Knabe et al., 2008; Joachimczak and Wróbel, 2008). The major difference with previous work is that our contribution emphasizes the analysis on internal dynamics rather than focusing on pure performance and generalization. To this end, the problem is briefly described and experimental results are analysed, with a particular emphasis on internal dynamics of GRN as well as the spatial resolution of the problem in terms of gene expressions.

### Relationship between spatiality and temporality

Two different target shapes are considered: a French flag (three vertical strips) and a Japanese flag (white background with a red centered circle), each with its specific properties regarding the possible impact of morphogen gradients on the GRN expression levels.

**The French flag** In this problem, two morphogen gradients are positioned horizontally and vertically. They allow a precise positioning of the cells in the environment on the x-axis and y-axis. However, the target flag is developed in the diagonal of the environment. It implies an adaptation of the regulatory network to utilize both morphogens.

The regulatory network is trained on a 9x5 flag (45 cells). The target flag is composed of 3 strips of the same size: a blue in the bottom left of the environment, a white in the center and a red in the top right part. Figure 3 shows the obtained result. The resulting image perfectly matches with

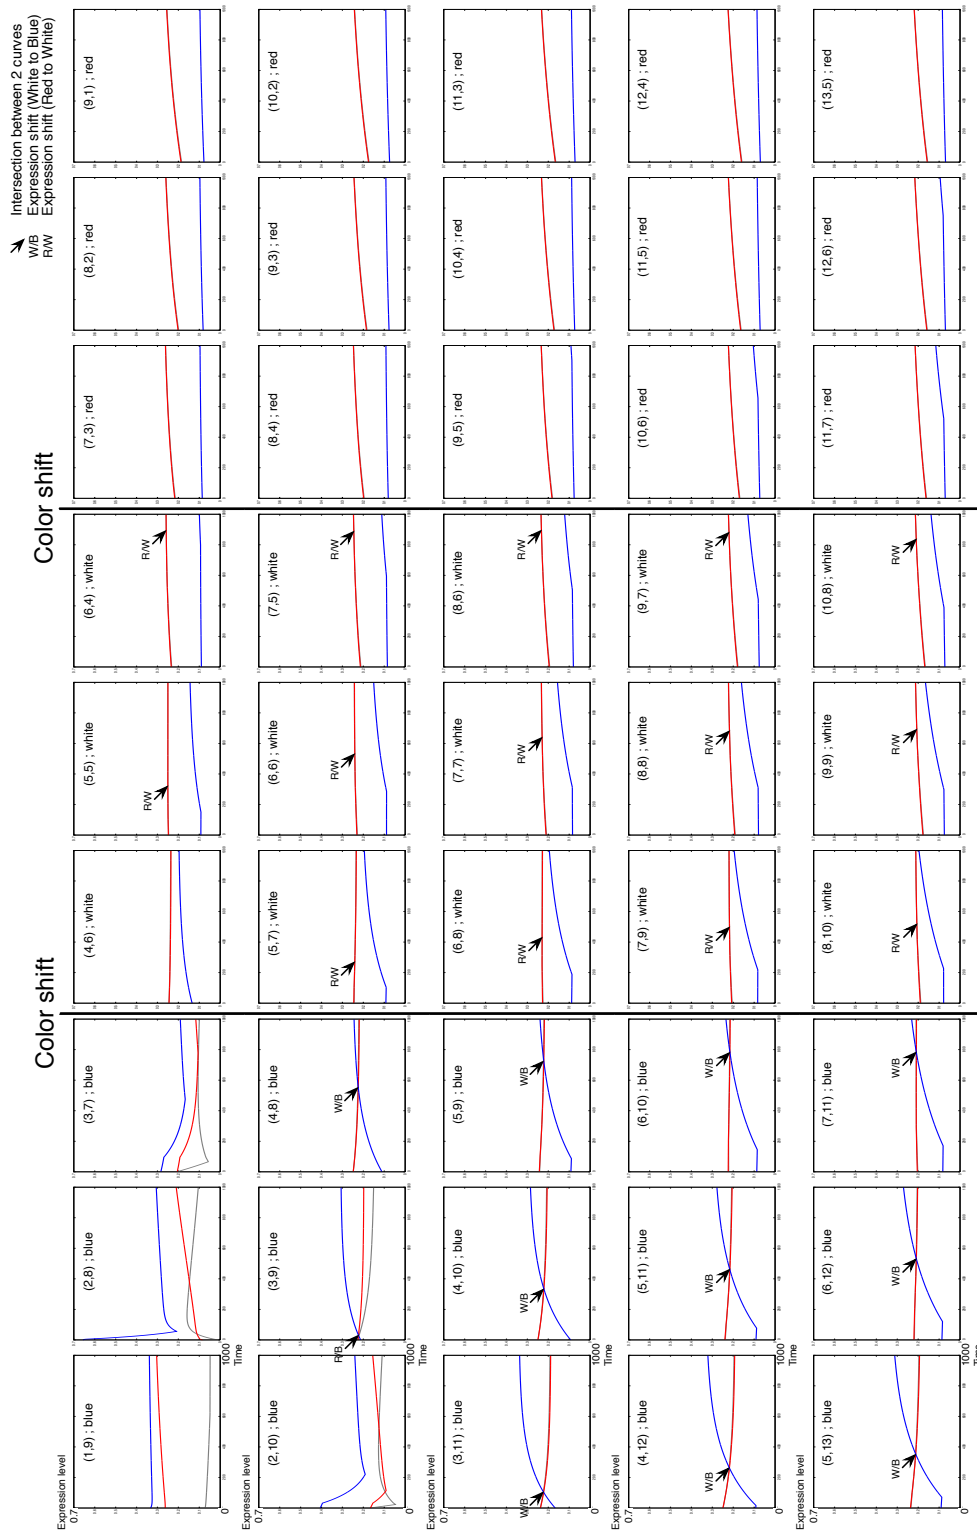

Figure 4: Variation of the gene expression levels over time for each cell of the organism. The curves correspond to the regulatory network activity of each cell of the French flag. The coordinate and the color of the cell are given by the title of each curve. We can observe a strong link between the delay of expression of appropriate gene and the distance to the color shift: the longer the distance to the color shift point, the faster the gene expression.

Figure 3: Development of the French flag

the target flag. To study the spatialization of the regulatory network, we extract all the curves of the color expression level over time of the regulatory network expressed in each 45 cell of the organism. These curves are presented in figure 4. The top left curve matches with the left corner blue cell of the organism in figure 3.

All these curves represent the variation of the three gene expression levels (blue, white and red) on the y-axis (scaled between 0 and 1) during the one thousand time steps of regulatory network's evolution. In the top left part of the figure, both morphogen orientations are represented according to the organism orientation.

It is interesting to notice the progressive softening of the blue curve in all curves and, at the opposite, the progressive increasing of the two other curves (red and white are almost overlapped). On the one hand, the transition between the blue curve and the white/red curves is very visible. On the other hand, the transition between white and red is hugely more smoothy. Both curves are very close all the time, except in the 5 top left curves. This exception is certainly due to a strong regulation shift in the regulatory network.

More relevant, the temporality of the color expression shifts is very observable. Considering only the blue and the white strips, the expression of the blue color is visible later and later in the regulatory network as the cell is closer to the white area.

The blue/white shift disappears from the curve when the cell must be white but we can assume by interpolation of the curves that the shift happens later. The same phenomenon is also present between the white and the red strips, as pointed out by the *R/W* black arrows. It exhibits the strong link between the temporality of the gene expression and the spatial-

ity of the problem provided by the morphogen gradients.

Figure 5 presents the extraction of the regulatory network of the best evolved candidate. The nodes represent two groups of genes: the regulation genes named G1 to G39 and the product genes (that will produce the color of the cell) named P1 to P99. The size of each node is proportional to its number of links. The architecture of this network is interesting to observe. First, almost all the genes are used. Only two genes (G23 and G33) are not linked to the regulatory network. It shows the total use of the genome and the complexity of the network extracted. Secondly, six genes (G5, G14, G16, G27, G28 and G38) are interfacing the regulatory network and all product genes except P2, which is directly linked to the regulatory network. The interface has not been coded in the network. It only emerged thanks to the evolutionary process. Lastly, in the regulatory area, three genes (G4, G25 and G26) play a central role and they are strongly connected to the rest of the regulatory area. This regulatory area is very complex with a lot of links between all the nodes. This complexity is due to the necessity to exploit both gradients (horizontal and vertical).

**The Japanese flag** In order to investigate the independence of the coordinate system to the temporality answer of the regulatory network, development of a japanese flag in a radial coordinate system is studied. The goal is thus to develop into an image with a red circle in the center of a white 13x9 rectangular shape (a total of 213 cells). The same three genes have been kept in order to establish the capacity of the GRN to switch off a particular gene.

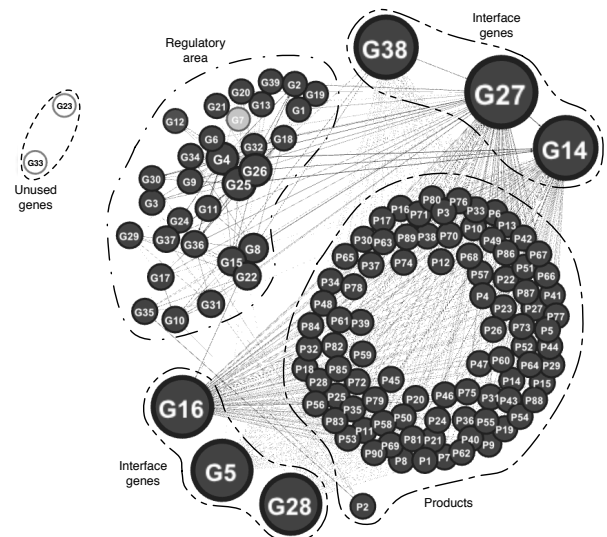

Figure 5: Gene regulatory network extracted from the best genome of the French flag with a threshold value of 19. G-genes represent regulation genes and P-genes represent the products of the regulatory network (a color expression).

Figure 6: Gene expression level curves of 5 cells of the Japanese flag's central line. The curves' legends indicate the coordinate and the color of the cell that correspond to the gene expression.

As previously, only 15 generations is required to obtain a near-perfect flag (with only 3 pixels wrong). Figure 7 illustrates the flag obtained.

As for the previously presented French flag, all the curves of the gene regulation have been extracted in order to study the link between the temporality of the regulation and the spacialization of the problem. Figure 6 shows the curves of gene expression levels of five cells of central line: 3 whites cells and 2 red.

We can observe that all the expression levels are very close (y-axis is zoomed on the interval  $[0, 0.4]$ ). The blue gene is also very strongly expressed even if not needed in this flag. Its inhibition by the regulatory network is correctly made but seems to be very weak. The same link between the temporality and the distance to the shift is also observable as on the French flag: the closer the colors shift, the later the gene expression levels shift. The same behavior is observable elsewhere on the flag and each transition stage can be obtained by rotation.

## Conclusions and Perspectives

The goal of this work was to investigate the use of Artificial GRN in the context of a spatial problem. We combined Banzhaf's GRN model to our own developmental model *Cell2Organ*, and experimental studies have been conducted on variations of the multi-cellular flag problem, a well-known benchmark in Artificial Embryogeny. Results from

Figure 7: Development of a Japanese flag with a radial gradient.

the experiments confirm the strong link between the temporality of the gene expressions in the regulatory network and spatial parameters of the problem. Indeed, change in the cell differentiation process among the organism is correlated by significant shifting in the GRN dynamics. The temporal aspect observed here also raises numerous question regarding the ability of a population of GRN to actually generate some desired behaviors. How many steps does it take to produce a correct output? What is the expressivity of such a system, in particular, how many basin of attractions can be encoded within one GRN template? Is it possible to have, depending on the context at hand, either a fast or a smooth shift between two regimes? These questions are of particular interest to explore further GRN-based control optimization problems (Joachimczak and Wróbel, 2010; Nicolau et al., 2010).

The complexity of the regulatory network obtained was also somewhat surprising and raises the question as to the evolvability of such a representation. The regulatory network needed a large number of P-genes (not restrained in these experiments) in order to find a solution to the problem. This may be a symptom of code bloat, a well-known problem of uncontrolled growth in variable length representations and definitely requires further studies, with possible investigations with respect to penalizing bloat without undermining the model's performance.

Lastly, spatial problems addressed here are relevant for this kind of detailed study, but have limited applications in the current form. However, the field of applications is large and examples from Biology give a good indications on the variety of problems to be addressed: cell differentiation into neurones, development of muscular cell, tissues, etc. In the context of computer modelling, understanding the intrinsic properties of GRN may be relevant in a variety of problems requiring complex temporal and spatial interactions. Indeed, because of their structure, regulatory networks could be more suitable for continuous problems than other behavior controllers such as artificial neural networks or classifier systems.

## Acknowledgements

The authors would like to thank Miguel Nicolau for his help regarding the implementation of the artificial GRN model.

### Abstract

In what ways can artificial life contribute to the scientific exploration of cognitive, affective and social processes? In what sense can synthetic models be relevant for the advancement of behavioral and cognitive sciences? This article addresses these questions by way of a case study — an interdisciplinary cooperation between developmental robotics and developmental psychology in the exploration of attachment bonds. Its main aim is to show how the synthetic study of cognition, as well as the synthetic study of life, can find in autopoietic cognitive biology more than a theory useful to inspire the synthetic modelling of the processes under inquiry. We argue that autopoiesis offers, not only to artificial life, but also to the behavioural and social sciences, an epistemological framework able to generate general criteria of relevance for synthetic models of living and cognitive processes. By “criteria of relevance” we mean criteria (a) valuable for the three main branches of artificial life (soft, hard, and wet) and (b) useful for determining the significance of the models each branch produces for the scientific exploration of life and cognition. On the basis of these criteria and their application to the case study presented, this article defines a range of different ways that synthetic, and particularly autopoiesis-based models, can be relevant to the inquiries of biological, behavioural and cognitive sciences.

### Introduction

In his seminal article of 1989, Christopher Langton introduces the “synthetic approach” (SA) as the methodology proper to artificial life (AL) — to “put living things together”, “rather than take [them] apart” (Langton 1989, p.40). The methodological agenda that he proposes extends the focus of biological research to what is missing in the analytic approach traditionally applied to living systems. However, the plan does not merely consist in extending the focus from individual to relational components’ properties; from matter to organization; from centralised mechanisms to distributed dynamics of self-organization, as scheduled by other 20<sup>th</sup> century biological research programs. Distinctively, AL’s SA further aims to enlarge biology’s perspective from terrestrial to alternative “made by man” forms of life, and to actually include in biological heuristics, besides the question “how does it work?”, the question “why this and not that?” The intent is to investigate the essential principles of life, and to deal with the main issues about life, by attempting to “recreate” living things and their phenomenology. In other words: building artificially embodied and situated models of living systems and

phenomena in order to explore, through experimental manipulation, aspects of life usually not accessible in natural systems and scenarios.

This foundational methodological plan still unifies the three main branches of AL developed over the last two decades, since “soft”, “hard”, and “wet” AL (Bedau, 2003, p. 505), in spite of their divergent methods, all continue to refer to the SA as their basic methodology, and tend to agree in its characterisation. In addition, all of them emphasise the genuinely scientific aspiration of this methodology, as opposed to the mainly technological purposes of other research programs within computer science, robotics and synthetic biology. Moreover, they tend to attribute to this methodology the same heuristic features,<sup>1</sup> which, very schematically, can be listed as follows:

(a) The programmatic inversion of the established order between analysis of behaviour and construction of models — the SA directing researchers to first embed their basic hypothesis on life and cognition in working artificial systems, then examine the behaviours they produce.

(b) The theoretical hypothesis that distinguishes between organisation and physical-chemical realisation of living and cognitive systems, and claims that these systems and their phenomenology can be recreated by implementing the former in new physical media i.e. artificial “embodiments” and “embedments”.

(c) The emergentist framework which grounds living and cognitive behaviours not within the systems displaying them, but in the interplay between three basic organisational levels of life and cognition: the systems, their elemental components, and the environment(s) with which the systems interact.

(d) The correlated production of simple and generative models of living and cognitive systems, that is, models able to generate complex and unexpected behaviours through rather simple internal mechanisms. The latter models are designed to create complexity, not by themselves, but by participating in systems-components-environment(s) interactive dynamics.

Over the last few years considerable work has been done to extend the applicability of the SA within the domain of cognition (e.g. Pfeifer and Scheier 2000; Lungarella et al. 2003; Bedau 2003; Cañamero 2005; Dawson 2004; Froese and Ziemke 2009). These developments pertain to cognitive

<sup>1</sup> Cf. e.g. Luisi 2010, Pfeifer and Scheier 2000; Dawson 2002, 2004; Damiano and Cañamero 2010.

processes *lato sensu* (i.e. including affective and social processes)<sup>2</sup> and re-propose, in new terms, the epistemological question of how relevant this methodology is for the scientific study of natural complex behaviours.

At the origin of AL, this issue was mainly focused on living processes; as Langton put it, “the notion of studying biology via the study of patently non-biological things is an idea that is hard for the traditional biological community to accept” (Langton 1989, p. 52). Today this has significantly changed. Contemporary academic biological departments integrate areas of research such as bio-computation or chemical synthetic biology. This expresses the wide acceptance, within biology, of interdisciplinary collaboration grounded in SA. The SA is also being widely applied to the study of cognitive processes within communities such as behaviour-based robotics and embodied artificial intelligence and artificial life. The situation is still different for the study of affective processes, where embodied synthetic models are still a minority. The application of the SA to this area is, to a large extent, hindered by the lack of principled reflection regarding a number of unanswered epistemological questions, and this constitute an obstacle to the integration of the SA among the explorative practices accepted by the scientific community as sources of valuable insights for cognitive and behavioural sciences. These include, for example, questions such as: in what sense can systems endowed with artificial “embodiments” and “embedments” generate effective models of natural cognitive, affective, and/or social processes? In which ways and in what sense can the synthetic study of these processes provide significant advancements with respect to other models? Which are the criteria that permit to define the relevance of synthetic models for the inquiries of cognitive and behavioural sciences?

This article addresses these questions with the intent of taking a first step towards providing epistemological groundings to the application of the SA to the affective (and more generally other cognitive and behavioural) sciences. More concretely, our aim is twofold: (1) to define an epistemological framework (that is, a set of principles of knowledge) able to ground SA as a relevant methodology that also encompasses affective processes, in addition to other biological and cognitive processes already studied by embodied AI and artificial life; and (2) to derive from this framework a set of criteria of relevance for the synthetic modelling of all these processes, that is, criteria (i) valuable for all three main branches of AL (*soft*, *hard*, and *wet* AL) and (ii) able to define the relevance of their models for the scientific exploration of natural living affective and cognitive phenomena. This article pursues these objectives not through general and speculative dissertation, but by discussing a concrete case study: an interdisciplinary model of the development of attachment (and more generally affective) bonds in the area of developmental robotics.

Through the presentation of this case study, Section 1 introduces the epistemological issue we intend to face, as well as the epistemological approach we adopt. Section 2 describes in detail two principles of knowledge that we propose as an epistemological framework able to ground the application of the SA to affective processes. These principles are extracted from autopoietic biology founded by Humberto Maturana and Francisco Varela in the 70s (Maturana and Varela 1987). It is

worth noticing that our use of autopoiesis is different from the usual one. We do not refer to Maturana and Varela’s theory of life and cognition, as is often done in AL, to take inspiration for producing specific models of living and cognitive processes. Instead, we refer to Maturana and Varela’s *theory of scientific knowledge*, and draw on some of its elements. This is in order to provide the synthetic study of life and the synthetic study of cognition with a shared epistemological framework, able to offer them common criteria of relevance for the models they produce. In Section 3 we formulate and discuss the meaning of these criteria. In Section 4 we apply them to the developmental robotics model of attachment bonds, and discuss its contribution to developmental psychology. In section 5 we present the range of different forms of relevance that synthetic models can have with regard to biological, cognitive and behavioural sciences.

### 1. An interdisciplinary exploration of attachment bonds

Developmental robotics is a relatively recent area of research, located at the intersection of robotics and developmental sciences, within which the SA plays a crucial role. This area uses studies from developmental sciences not simply to construct “more autonomous, adaptable and sociable robotic systems” (Lungarella et al. 2003), but also to gain a deeper understanding of developmental processes. One of the programmatic goals of developmental robotics is to employ robots as tools to investigate, test and possibly further elaborate, in an interdisciplinary way, theories of development proposed by these sciences (Pfeifer and Scheier 1999, Pfeifer 2002, Sporns 2003, Cañamero 2005). This expresses the originality of this emerging area, which intends to use developmental theories not only for engineering purposes (to create better adaptive robotic systems), but also for genuinely scientific purposes, through the extension of the SA to cognitive developmental processes *lato sensu*.

Within this framework, our research on the development of attachment bonds provides a good example of research that intends to explicitly address these two goals (Cañamero et al. 2006), and this for the following main reasons.

Firstly, this kind of inquiry allows researchers to face one of the central issues that need to be successfully addressed to advance in the development of social robotics, that is, how to design robots that could learn from us, be accepted by us as social partners, and be able to adapt to our ever-changing social environments. The developmental approach deals with this issue on the basis of the idea that the most successful example of adaptation into our social and technological environment, without much prior knowledge, is given by infants. Following this approach, researchers have, for example, successfully managed to design robots that use algorithms to learn and adapt to new sensorimotor pairings (Berthouze and Lungarella 2004; Blanchard and Cañamero 2005; Andry et al. 2009; Hiolle et al. 2007). Other contributors have focused more closely on how developmental psychology describes infant development, investigating how infants explore and discover new features of the environment, particularly through drives like curiosity (Oudeyer et al. 2007) and seeking wellbeing through affect-driven interactions with objects and people (Blanchard and Cañamero 2005, 2006; Cañamero et al. 2006). Indeed, the latter contributions are addressing the issue of how positive affect, such as providing comfort, can promote an efficient and

<sup>2</sup> Cf. e.g. Nunez and Freeman 1999. In this article, when we refer to cognitive processes, we always refer to them *lato sensu*.

consistent learning experience, depending on the environment and especially the behaviour of the social partner.

Developmental robotics research on attachment bonds arose within this context, and, in accordance with the general orientation of the area, has a second goal: it also aims at contributing to the advancement of developmental psychology through the design of adaptive social robots modelled using scenarios, parameters and metrics that are also relevant to, and used by developmental comparative psychologists for, the study of attachment bonds in (human and non-human primate) infants. This modelling approach gives rise to robots that behave and interact with humans in ways that are comparable to young infants (in the specific variables of the phenomenon under investigation), and therefore could be used as tools to investigate and possibly further develop theoretical models about attachment bonds.

In the reminder of this section we briefly summarize the developmental robotics research on attachment bonds that we undertook within the Feelix Growing Project (<http://www.feelix-growing.org/>) in collaboration with developmental and comparative psychologists,<sup>3</sup> and are continuing within the ALIZ-E Project (<http://www.aliz-e.org/>). This work focuses on the mechanisms underlying the establishment and development of attachment bonds in the first two years of age, which has implications for all phases of affective development. As this paper is directed to introduce the epistemological issues related to the extension of SA to cognitive development, we do not provide here the technical details presented in other articles; for technical details, we refer the reader, for example, to (Cañamero *et al.* 2006; Hiolle *et al.* 2006, 2007; Hiolle and Cañamero 2007).

### 1.1 Development of attachment bonds

Human infants grow and discover their new environment most often accompanied by (or not far from) their mothers or primary caregivers. The skills they learn, and the objects and agents they encounter, are surely presented and assimilated within their cognitive and emotional experience with the constant help and assistance of these adult human beings alongside them. Attachment was originally defined (Bowlby 1969) as the affective tie between the infant and its primary caregiver which offers security and comfort when needed. In the last decades, developmental psychology has been trying to study how this affective tie influences cognitive and affective development of young children. This research has produced critical and revised versions of Bowlby's theory, which point out the complexity of attachment processes, as well as the dynamical and inter-individual character of the "dyad" child-caretaker (e.g. Tronick 2007; Keller 2008). They tend to describe this dyad as an inter-individual system whose components are involved in a dynamic co-determination which shapes the way the child interacts with his/her (social) environment, and re-shapes the way in which the care-giver(s) interact with the child. These critical developments strongly converge with the SA's assumption about the generation of complex behaviours,<sup>4</sup> and constitute the body of work that we took inspiration from. The remainder of

this section briefly introduces the properties of attachment bonds we used and the robot model we produced.

### 1.2 Attachment bonds in infants

One of the main roles of attachment bonds is to provide mechanisms that permit to regulate ("negative") affective state, and particularly arousal, setting the grounds for the development of emotion regulation later in life. We therefore focused on arousal and its regulation in our model. This essential variable was designed to relate to the notion of excitement as defined in (Sroufe 1996), which, in the early months of life, is neither a positive nor a negative emotion or affect, but refers to the level of internal activity and external stimulations experienced by the infant. A high and sustained level would be too demanding and challenging, while a low level would not give rise to fruitful behaviour. Thus, maintaining a good level of this variable is desirable. This internal variable is close to the concept of arousal (Berlyne 1960), relating to the theory of optimal arousal, and the inverted U-shape hypothesis (Anderson 1990), where mammals try to maintain on average their arousal at a middle level where their physiology is optimal. In our investigation of infant development, the notion of arousal is very appropriate, as it is used in developmental psychology to assess emotional intelligence in newborns and its development (Brazelton and Nugent 1995). However, the notion of arousal is often used as a dimension of the two or sometimes three dimensions usually adopted in models based on the circumflex model of emotions (Russel 1980), such as in (Breazeal and Scassellati 2002). In this kind of model, arousal is an orthogonal dimension to the valence of percepts and behaviours, and the model offers a one-to-one mapping from a two dimensional vector from the arousal/valence space to a predefined emotion. In our work, however, we do not use the notion of arousal in the same way as these models. Instead, we see arousal as a variable related to internal activity, in terms of learning experience, which is implicitly tied to external perceptions, some being more stimulating than others, according to familiarity and complexity.

The robotics model that we designed is based on the notion of arousal, which we associated with the learning experience of the robot and how stimulating or familiar the experienced environment is — namely, the current sensorimotor state. To this end, our model assesses whether the current percepts are being correctly memorised and recalled, and this directly influences the arousal level of the robot: novelty increases arousal, familiarity decreases it. The robot does not have explicit drives or motivations beyond exploring the environment, and its behaviour is a function of the level of arousal. The human, playing the role of a "caregiver", also has an impact on the arousal of the robot, in accordance with the secure base paradigm: the arousal level is decreased when the human provides comfort to the robot, either via direct tactile contact or by being present on its visual field. This robot-caregiver system is a dynamical system that present the essential elements needed to reflect and test the hypothesis concerning the attachment bonds and caregiving influences on it: unfamiliar events and stimuli increase the arousal and provoke distress, and the attachment figure can then relieve this distress with comfort. Whenever the arousal is low, the infant-

<sup>3</sup> Within the FEELIX GROWING project we worked in collaboration with Kim Bard and Jacqueline Nadel.

<sup>4</sup> Cf. the Introduction of this paper, point (d) and (Damiano and Cañamero 2009).

robot would keep exploring its environment as long as there are unknown features, in order to further its learning experience.

### 1.3 Robot Model

The robotic system is based on a few simple hypotheses, as stated above. Firstly, the robot's only "motivation" is to learn the features it can perceive in its environment. The level of arousal of the robot is calculated as a function of the familiarity and novelty of these features. The arousal rises when the robot is stimulated, and decreases when the attachment figure provides comfort visually or via tactile contact. When the level of arousal is low, the robot will seek stimulation and carry on exploring. The learning system of the robot uses two different well-known neural networks, a Kohonen Map (Kohonen 1997) and a Hopfield-like associative memory (Davey and Adams 2004, Hopfield 1982). The arousal level depends directly on the variation of the weights of the Kohonen Map, and on the accuracy of the associative memory. Indeed, a high variation of the weights is consequential of the robot discovering new features, and a mismatch between the output of the associative memory and the current perception is proportional to the novelty thereof. The arousal level is calculated as the exponential average of these two contributions over a predefined time window. When the caregiver touches the sensors on the back of the robot, the arousal level decreases exponentially and faster than it could increase whilst being over-stimulated. According to the arousal level and predefined thresholds, the robot behaves as follows. When the level is in a medium range, the robot remains still and attends to the current stimuli. Finally, when the level is high, due to too many and familiar stimuli, the robot is "distressed" and it will seek comfort from its caregiver.

Using this robot model, we undertook a series of studies focused on studying different aspects of the development of attachment bonds with one or more human caregivers.. These studies rest on the interdisciplinary design of experimental scenarios, with the aim to provide insight and feedback to all the different disciplines involved. Several crucial aspects of the development of attachment bonds were under inquiry. These included the development of different attachment profiles; the influence of these different profiles on exploratory behaviors; the role of attachment bonds in the development of sensorimotor associations; and the development of attachment bonds in the presence of multiple caregivers (Cañamero *et al.*, 2003; Hiolle *et al.* 2006, 2007; Hiolle and Cañamero, 2007).

### 1.4 The epistemological issue

The relevance of these studies for the construction of robots able to develop their skills and behaviours dependently on the interactions with their users is quite evident. However, considering the level of abstraction and simplification characterising the robotic architecture described above, the restricted possibilities of interaction of the "baby" robot with its human partner(s) and environment, the limited aspects of development of attachment bonds taken into account by the robot model, can we say that these studies are able to produce relevant feedback for human developmental psychology? Are there ways and conditions in which this "baby" robot can be fruitfully used to model and explore attachment phenomenology in humans?

If we refer to the widespread, and in our opinion incorrect, idea that a model system should "represent" the target system in all its aspects and behaviours, we have to answer in the negative. This notion, grounded in the classical "representationalist" scientific epistemology is also strongly questioned by the epistemological debate about synthetic modelling. The latter points out not only that necessarily scientific modelling fails in representing everything about target systems, but also that this is not its main goal. The basic purpose of scientific modelling is not to replicate the target system, but to investigate what are its relevant features. As in the case of synthetic modelling, the goal is to embed, in a model system, the scientific hypotheses about these features, and to test these hypotheses.

This argument has been proposed by both representationalist and non-representationalist epistemological approaches to AL. While the former use it to propose weak versions of the classical idea that scientific representation should be an exhaustive reflection of nature (e.g. Webb 2001), the latter use this argument to express the thesis that representationalism is not an appropriate epistemology for AL (e.g. Riegler 1992). According to the latter view, representationalist epistemological notions, based on the ideal of a science exploring objects independent from the observer, cannot orient the scientific practice grounded in the SA. Indeed, this methodology promotes a form of scientific knowledge which actively creates, and does not passively reflect, the phenomena explored. It refers to an observer who is the constructor, and not the old-fashion representationalist "spectator", of the systems he investigates. Moreover, the SA discards the representationalist dichotomy subjective/objective, as it proposes a way of doing science in which *facts* converge with *artefacts*, *discovery* corresponds to *invention*, *objective evidence* is not separable from *subjective construction*, and spontaneous manifestations of nature can be explored in the behaviour of artificial systems. As we showed in detail elsewhere (Damiano and Cañamero 2010), these remarks tend to lead non-representationalist approaches to AL that take inspiration from constructivist theories of scientific knowledge. These characterise science, in all its forms, as an activity of construction of objects of research (cf. e.g. Glasersfeld, 1995), and therefore propose to science epistemological notions and principles of knowledge which can be considered particularly appropriate for grounding, and supporting the scientific practice grounded in, the SA.

Our approach to the epistemological grounding of the SA belongs to this non-representationalist orientation. To address the issue of the relevance of synthetic models, like the robotic model presented above, for the inquiries of cognitive and behavioural sciences, we choose to refer to *autopoietic epistemology* (Maturana and Varela 1987). This is one of the best expressions of the constructivist epistemology developed across AL's scientific genealogy (Damiano and Cañamero 2010), and, as we argue, can provide shared groundings and common criteria of relevance to the synthetic study of life as well as to the synthetic study of affect and more generally cognition.

## 2. Grounding the SA in autopoietic biology

The connection between autopoietic cognitive biology and AL is strong. As already mentioned, Maturana and Varela provided more than an emergentist theory of life and an emergentist theory of cognition which are useful to inspire the production

of synthetic models of biological and cognitive processes. As often neglected (even by AL researchers who take inspiration from these theories), Maturana and Varela elaborated an explicit constructivist theory of scientific knowledge, which proposes the SA as the proper methodology to investigate both life and cognition, at the theoretical level as well as the experimental one. This autopoietic version of the SA, formulated more than a decade before the Langtonian one, is based on epistemological notions and principles which give expression to the intuition at the basis of Langton's AL program, and, in this sense, can be considered as appropriate epistemological groundings for AL's SA, both in the domain of life and in that of cognition.

On the basis of these considerations, we saw in Maturana and Varela's production a source of epistemological elements useful to provide a shared epistemological framework to the synthetic study of life and that of cognition. In particular, we extracted from autopoiesis two principles which, as we try to show in the remainder of this section, are particularly significant with regard to this goal. Below we summarize these (well-known, to a large part of the AL community) principles, to make the paper self-contained and help readers who might not be totally familiar with this approach.

### 2.1 Principle 1: Explaining = Constructing

The first principle proposes an operational definition of scientific explanation, according to which explaining a phenomenon amounts to proposing a mechanism able to produce it (cf. e.g. Maturana and Varela 1987, chapter 1). Visibly, the aim of this postulate is to extend the classic view of scientific explanation. It juxtaposes the traditional notion "explaining = predicting" to a constructivist one, which, proposing the equation "explaining = constructing", can be applied to systems exceeding scientific capabilities of calculation and prevision. Requiring models able not to *predict*, but to *generate* the natural processes under inquiry, the principle locates the focus of scientific explanation not on *actual*, but on *possible* behaviours of the systems explored. That is, it grounds a category of scientific descriptions which is particularly appropriate for living and cognitive systems, since the kind of characterization it proposes cannot be affected by these systems unpredictability. AL's SA can be legitimately included within this category, for it presents the basic distinctive features characterizing the paradigmatic constructive description of nature grounded by autopoiesis in this principle. In particular, it shares the distinctive features of the main example of constructive explanation provided by Maturana and Varela, namely, the autopoietic explanation of life. Very schematically: *raison d'être* (the natural phenomena it intends to describe are untreatable through the classical predictive modelling), epistemological grounding (the constructivist postulate according to which knowing scientifically means to build objects of research), heuristic gender (operational characterizations of the natural processes explored), procedure (definition of a generator for the phenomenology to be described, and exploration of the phenomenology it produces), and, finally, the appellation "synthetic".

In Maturana and Varela's literature, the introduction of this kind of scientific characterization is described as implying a long series of shifts in classical scientific epistemology, which produce a new emphasis not only on *construction* instead of

*representation*, on *generation* instead of *prediction*, on *possibility* instead of *actuality*, but also on *synthesis* instead of *analysis*. Indeed, in Maturana and Varela's production, the term *synthesis* defines the methodological orientation of autopoietic biology's theoretical program, just like, in Langton's literature, it defines the methodological orientation of AL's program.

On the basis of its principle of scientific explanation, autopoietic biology plans to formulate a procedurally new definition of life, which, instead of listing the main features of living systems, specifies a dynamical mechanism able to produce their phenomenology. Maturana and Varela call this kind of definition "synthetic", to distinguish it from the traditional "analytic" definitions of life presenting detailed lists of properties. The condition that this synthetic definition has to satisfy to be considered an appropriate explanation of life is expressed in terms of its theoretical productivity. The mechanism that it specifies has to show the capability of creating, from a set of elemental components, an entire biological domain. That is, it has to manifest the ability of generating, by the dynamical coordination of a set of elements, a minimal cellular system with its characteristic phenomenology. That is: not only cellular self-production, but, through this, also reproduction and evolution, to the extent to be able of producing, step by step, a differentiated living domain, as complex and populated as the terrestrial one.

This is the kind of scientific modelling of the living that Langton's characterization of AL intends to implement too, not at the level of a purely theoretical construction, but at that of an empirical one: the synthesis of "any and all biological phenomena, from viral self-assembly to the evolution of the entire biosphere", without restriction to carbon-chain chemistry. As in the case of Maturana and Varela, Langton's program is that of a constructive and universal biology, which converges with autopoietic biology not only on the basic epistemological principle of scientific explanation, but also on the principle of biology's universalisation. "Life is (...) a result of organization of matter, rather than something that inheres in the matter itself" (Langton 1989, p. 53).

### 2.2 Principle 2: Organization ≠ Structure

The second autopoietic principle we consider pertinent for the epistemological grounding of the SA is a theoretical postulate with a significant epistemological value. Its basic content is the distinction between two notions — *organization* and *structure*. Simplifying the original autopoietic formulation (Maturana and Varela 1987, chapter 2), we can put it as follows: the *organization* of a living system is its relational frame, that is, the network of relations which define the system as a unity of components; the *structure* of a living system is its materialization, given by the actual components and their interconnections.

This distinction is not a theoretical novelty introduced by Maturana and Varela. A first complete formulation can be attributed to Jean Piaget (1967, chapter 4), who proposed this conceptual distinction as the theoretical key to comprehend biological systems as dynamical, since it corresponds to the distinction between the invariant and the variant aspects of their dynamics. Piaget remarked that living systems can be considered dynamical systems endowed with a peculiarity: all their elementary components permanently change, while systems, as relational unities of components, remain. This, as

Piaget pointed out, can be affirmed at both the ontogenetic and the phylogenetic levels. The relational unity remains unchanged not only in the permanent flux of physical-chemical components typical of biological organisms, but also during the ontogenetic transformations which can make a living system unrecognisable from one observation to the next. Moreover, this relational unity is transmitted through reproduction and remains unchanged generation after generation. Indeed, this relational unity is the invariant of the biological dynamics and therefore the lowest common denominator of living systems. Distinguishing this invariant relational frame from the changeable materializations of living systems, and determining its configuration, amounts to isolating an element which can be used to define the class of biological systems.

These remarks point out the epistemological relevance of the distinction between organization and structure, which is at least two-fold. Firstly, this distinction allows biological research to hypothesize a defined mechanism for living dynamics (i.e. a mechanism creating organizational invariance through permanent structural variation), and therefore opens the possibility of a constructive explanation of life. Secondly, it generates significant insights about the SA's relevance to the study of natural living and cognitive processes, as it implies that: (a) in principle the materialization (structure) of living systems can be manifold; (b) artificial systems displaying the same organisation as living systems, and realising it in a different structure, have to be considered as belonging to the class of living systems.<sup>5</sup>

Thus, the autopoietic distinction between organisation and structure offers a theoretical ground to the thesis — “the big claim” — through which Langton expresses AL's aspiration: “a properly organized set of artificial primitives carrying out the same functional roles as the bio-molecules in natural living systems will support a process that will be ‘alive’ in the same way that natural organisms are alive. AL will therefore be genuine life — it will simply be made of different stuff than the life that has evolved here on Earth.” (Langton 1989, p. 69)

### 2.3 Autopoiesis and the extension of the SA to the domain of cognition

Autopoietic biology does not limit itself to formulating principles that support Langton's initial AL program. It also supports the extension of this program to cognitive processes. The intent of “naturalising cognition” led Maturana and Varela to identify living systems as cognitive systems, since their general process of self-production (i.e. autopoiesis) corresponds to a permanent process of interaction with the environment and other systems (structural coupling) that allows living systems to survive. The conceptualisation of this process as a process of cognition is at the basis of the cognitive biology that Maturana and Varela developed as an extension of their theory of life, fathering the nascent “embodied cognitive science” (Clark 1999). According to this view, the phenomenology that has to be produced by the autopoietic synthetic definition of life includes not only all the biological, but also all the cognitive

<sup>5</sup> The thesis of the multiple material realization of organization implies a convergence between autopoiesis and functionalism. There is no room here for a detailed comparison. However it is worth noticing that autopoiesis and functionalism have different views about the implications of this thesis. For example, autopoiesis, differently from functionalism, emphasizes the dependence of cognition on the agent's embodiment.

phenomenology *lato sensu* (Maturana and Varela 1987). In this sense, the autopoietic principle of the constructive explanation and the autopoietic distinction between organisation and structure offer a grounding framework not only to the synthetic study of life, but also to the synthetic study of cognition *lato sensu*.

### 3. Two criteria of relevance for the SA

The two autopoietic principles presented above can be transformed into two criteria for use in determining the relevance of the SA's implementations to the study of life and cognition.

#### 3.1 – “Explaining = Constructing”: phenomenological relevance<sup>6</sup>

From the principle of scientific explanation extracted from autopoietic biology's production (P1: *To explain scientifically is to provide a mechanism able to produce the phenomenology to be explained*) can be derived a criterion of “phenomenological relevance” for synthetic models of natural living and cognitive phenomena, according to which:

(C1) *A synthetic model is relevant at a phenomenological level if it provides a mechanism which produces (according to explicit parameters) the same phenomenology as the living or cognitive phenomenology under inquiry.*

The appellation “phenomenological relevance” expresses the fact that this criterion requires only a relation of identity (defined by explicit parameters) between the phenomenology produced synthetically and the natural phenomenology under inquiry. This means that (C1) does not impose any constraints on the biological plausibility of the synthetic mechanism by which the phenomenology under exploration is produced. Therefore, if (C1) is not correlated to a criterion which requires the biological plausibility of synthetic models, and specifies what this plausibility consists of, then (C1) cannot warrant that these models offer a biologically plausible explanation of the target processes, and that they do not simply imitate the phenomenology under inquiry.

However, from autopoietic biology we can also extract a principle to differentiate phenomenologically relevant models on the basis of their respective operational explanatory powers — that is, on the basis of their capability of providing an operational explanation of the phenomena under inquiry. This principle, belonging to the autopoietic theory of scientific explanation (Maturana and Varela 1987, chapter1; Maturana 1988), associates the operational explanatory power of a model to its “progressive” character, that is, its capability of producing, besides the phenomenology under inquiry, also other phenomena belonging to the same domain.<sup>7</sup> In this sense, autopoietic epistemology provides a principle of evolution to the phenomenologically relevant synthetic modeling of living and cognitive processes, which can orient the choice between different models referred to the same phenomenological domain. That is, on the basis of the quantity of supplementary phenomena, that they are able to produce, these models can be considered more or less progressive (that is, more or less operationally explanatory) than another models.

<sup>6</sup> Here the adjective ‘phenomenological’ has the meaning of ‘relative to the phenomenology under inquiry’.

<sup>7</sup> We use the term ‘progressive’ in accordance with Lakatosian philosophy.

According to this principle, we have to distinguish two basic kinds of phenomenologically relevant models. They can be respectively defined as follows:

(1) *minimal phenomenological models*, which produce only the phenomenology under inquiry, and therefore have a minimal operational explanatory power;

(2) *progressive phenomenological models*, which produce, besides the phenomenology under inquiry, other phenomena belonging to the same domain, and have an operational explanatory power proportioned to the quantity of supplementary phenomena produced.

Evolution towards better phenomenologically relevant models corresponds to evolution towards models endowed with a higher operational explanatory power, but not necessarily towards biologically plausible models. Indeed, even if a greater operational explanatory power could be considered as a clue of greater biological plausibility, this last remains uncertain in absence of a criterion which specifies what this plausibility consists of. A synthetic progressive model, in itself, could be useful for the traditional scientific exploration of living and cognitive processes as it could offer not a biologically plausible explanation of these processes, but a source of inspiration for the production of hypotheses about the mechanisms underlying them.

### 3.2 “Organization ≠ Structure”: relevance in the strong sense

As pointed out before, the autopoietic distinction between organization and structure implies that (P2.i) *All living and cognitive systems share the same organisation, but not necessarily the same structure*, and therefore that (P2.ii) *Artificial systems which display a different structure, but the same organisation as living and cognitive systems, have to be considered legitimately belonging to the class of living systems*. Thus, the autopoietic distinction between organization and structure produces a criterion of relevance for synthetic models of living and cognitive systems. In fact, in accordance with (P2.ii), the former can be considered *strong models* of the latter if they share the same organisation, since, in this case, they constitute *specimens* of the class of living and cognitive systems.

We can refer to this criterion as to a criterion of *organisational relevance*, which warrants the biological plausibility of synthetic models. Associated to the criterion of *phenomenological relevance*, it produces the criterion of “relevance in the strong sense”:

(C2) *Synthetic models are relevant in the strong sense if, besides providing mechanisms which generate the phenomenology under inquiry (phenomenological relevance), they present (according to some explicit theory of living and/or cognitive organisation) the same organisation as living and cognitive systems*.

Satisfying this criterion is indeed a hard challenge for AL, which, of course, always has to be faced referencing one or more theories of biological and/or cognitive organisation, and always in an approximate way due to the intrinsic limits of these theories, the varieties of their interpretations, and the limited possibilities of their implementation. In this sense, relevance in the proper sense has to be considered for artificial life more a regulative ideal than a concretely attainable goal.

## 4. Interactive phenomenological relevance

If attachment phenomenology is defined as the closed set of phenomena normally used to exemplify it (e.g. seeking the proximity of the caregiver, developing stress in situation of separation and developing different attachment profiles depending on caregiver behaviour), then the robot model can be considered to (roughly) satisfy (C1). But, as far as we tested it, this model does not have a progressive character, and cannot be considered biologically plausible according to (C2). Therefore we are led to attribute it a *minimal phenomenological relevance* with regard to attachment behaviours, and to consider it as simply imitating them.

However the robot model does more than this when the system under consideration is the *human-robot interacting dyad*. Using this model in experiments involving humans in the role of caregivers, the resulting evidence suggests that it has further scientific potential, related not to its operational explanatory power or its biological plausibility, but to its capability of dynamically interacting with human agents. In fact, the “baby” robot appears able to engage humans in *interactive dynamics* which can be of scientific interest for the developmental psychology inquiry on attachment bonds (Hiolle *et al.* 2008). That is, it offers to developmental psychology the possibility of experimentally manipulating and exploring, in human agents, aspects of the attachment phenomenology that can be difficultly accessible in the classical psychological scenarios of research. An example of these processes can be found in human caregivers’ reactions to different attachment profiles. This is an aspect of the attachment phenomenology that developmental psychology could study through robot models like the one presented above, as emerged from our interdisciplinary exploration of attachment bonds.

These remarks lead us to introduce a new kind of minimal phenomenological model. These can be defined as *interactive phenomenological models*: models able to synthetically produce the phenomenology under inquiry, and, through the expression of this phenomenology, to engage natural biological and/or cognitive systems in interactive dynamics which (according to some explicit parameter) prove interesting for the scientific exploration of the natural phenomenology under inquiry.<sup>8</sup> As such, this kind of minimal phenomenological model can concretely contribute to biological, behavioural and cognitive science’s inquiries on natural living and/or cognitive processes, as synthetic tools that, through their capability of interacting with natural living and/or cognitive systems, can support the experimental manipulation and investigation of their processes.

## 5. Conclusions

This article proposes a constructivist solution to the issue of providing epistemological groundings for the application of the SA to affective and social processes. This solution consists of an epistemological framework extracted by autopoietic epistemology, able to provide to both the synthetic study of life and the synthetic study of cognition with (1) shared grounding principles of knowledge, and (2) shared general criteria useful to define the relevance of (soft, hard, and wetware) synthetic

<sup>8</sup> Soft AL’s production is rich of examples of virtual agents interacting with human agents, and able to engage them in interactive dynamics which could be interesting from a scientific point of view. Examples of synthetic systems able to interact with natural systems are emerging also in wet AL (cfr. e.g. Kaneda *et al.* 2009 about interactions between synthetic models of minimal cells and cultured cells).

models for the exploration of life and cognition. We showed how these criteria open a space of relevance for the synthetic modelling of life and cognition defined by two extremes. The “lower” extreme is *minimal phenomenological relevance*, which characterises models that, by reproducing synthetically the natural phenomenology under inquiry, offer an operational explanation of these process, but, as they do not have biological plausibility, have to be considered synthetic imitations of them. The “upper” extreme, which has to be considered more a regulative ideal, than a concretely attainable goal, is (2) *relevance in the strong sense*. It characterises models that reproduce synthetically the natural phenomenology under inquiry, and, as they display the same organisation as living and/or cognitive systems, can be considered to belong to the class of living and/or cognitive systems. We argued that, within this space, AL can produce two kinds of synthetic models that could be of interest for its interdisciplinary cooperation with biological, behavioural and cognitive science. The first is given by models characterised by a *progressive phenomenological relevance*, that is, the capability of producing not only the phenomenology under inquiry, but also other phenomena belonging to the same domain. These models have a significant operational explanatory power, and, dependent on their biological plausibility, can prove useful for biological, behavioural or cognitive sciences as a source of inspiration for the definition of the mechanism underlying the phenomenology under inquiry. The second kind is given by models characterised by a *interactive phenomenological relevance*, that is, the capability of producing synthetically the phenomena under inquiry, and, through this, engaging natural systems in interactive dynamics that prove useful to experimentally investigate, in natural systems, at least some aspects of the phenomenology under inquiry.

## Abstract

The mutation networks observed in biological systems have the properties of small-world networks. These properties of short average path length and high transitivity confer a favourable exploration of mutation space. Any evolvable string-based ALife system (for example stringmol, typogenetics, Tierra, or Avida) uses a substitution network either implicitly or explicitly. Current ALife simulations use either regular or random mutations schemes. We have previously discussed the requirement for small-world substitution networks for ALife simulations. In this paper, we explore the effects of rewiring the stringmol mutation lattice on the evolution of a self-replicating molecule.

## Introduction

Mutation is an essential component of any evolvable system, allowing it to explore its fitness landscape and therefore to evolve. The evolutionary dynamics of a system are thus critically dependent upon its mutation strategy.

Amino acid substitution matrices (Dayhoff et al., 1978; Henikoff and Henikoff, 1992) give an indication of the likelihood of observing an amino acid substitution in homologous proteins. Ideally, a substitution matrix should allow any token to mutate to any other token relatively easily (thus allowing a rapid exploration of the fitness landscape); whilst simultaneously favouring mutations to tokens of similar function (thus minimising the chance of deleterious mutations). Networks that exhibit these properties of short average path length and high clustering coefficient were described by Watts and Strogatz (Watts and Strogatz, 1998). We have previously demonstrated that biological mutation networks exhibit these small-world properties (Droop and Hickinbotham, 2011).

Although biological mutation networks exhibit small-world properties, ALife simulation mutation schemes do not. The typogenetics (Gwak and Wee, 2007) and Avida (Johnson and Wilke, 2004) systems use essentially random mutation schemes. By contrast, the stringmol (Hickinbotham et al., 2010a,b) and Tierra (Ray, 1991) systems use regular mutation networks. Figure 1 shows the mutation lattices used by the stringmol and Tierra systems.

Figure 1: The mutation networks used by the stringmol and Tierra ALife simulations. The stringmol lattice shown here has  $k = 4$ .

The stringmol mutation network is constructed as a complete lattice with each node connected to its  $k$  nearest neighbours (in this case  $k = 4$ ). The Tierra network is based upon binary bit flip operations: each opcode can flip a single binary digit. Any mutation scheme can be represented by a graph where possible substitutions between tokens are represented as edges. The Tierra opcode lattice in figure 1 shows that although the neighbours for each opcode were carefully chosen to allow ‘sensible’ mutations, the mutation network topology is nonetheless regular.

To test this idea, we implemented a small-world mutation network topology for the stringmol system using the rewiring scheme devised by Watts and Strogatz (Watts and Strogatz, 1998). Here, we present the findings from this study, and discuss the effects of different mutation models upon the stringmol system.

## Methods

Multiple networks were created for the stringmol system using the Watts and Strogatz (1998) rewiring model as described previously (Droop and Hickinbotham, 2011). The stringmol regular mutation lattice with  $k = 4$  was used to perform all analyses. The mutation rate is fixed for all trials. Four different rewiring probabilities ( $p_{\text{reg}} = 0$ ,  $p_{\text{small}} = 0.1$ ,  $p_{\text{mid}} = 0.3$  and  $p_{\text{rand}} = 1$ ) were used when cre-

ating networks. The  $p_{\text{reg}}$  network is the same regular lattice as used previously in stringmol. The  $p_{\text{small}}$  and  $p_{\text{mid}}$  networks fall within in the small-world region for networks of this size (Droop and Hickinbotham, 2011). The  $p_{\text{rand}}$  network is completely random. 100 rewiring replicates were created for  $p_{\text{small}}$ ,  $p_{\text{mid}}$  and  $p_{\text{rand}}$ ; whilst only a single trial of  $p_{\text{reg}}$  was performed (as there is only one possible network). For each replicate experiment, the stringmol simulation run for a maximum of  $1.2 \times 10^9$  time steps with 300 trials.

Summary statistics were collected for each trial. Four statistics were used to describe each individual trial. The *life time* is the total number of time steps over which the trial survives. The *epoch count* is the number of epochs (defined as a continuous period of time in which a particular string species is the most common). The *epoch length* is the length of each epoch. The *edit distance* is a measure of the mutational distance that the trial has been able to cover. The edit distance is calculated as the Smith-Waterman alignment score between the initial string and the dominant string (only counting strings greater than 10 letters, thus ignoring short ‘pathogenic’ strings) for the last epoch of length  $\geq 50000$ , normalised to the length of the string.

## Results

Box plots (McGill et al., 1978) of the results for the summary statistics outlined above are given in figure 2. The trend across figures 2A, B and C is consistent: the more random the mutation network, the shorter the simulation life time and fewer (shorter) epochs are present. The reduction in life time indicates that large amounts of energy are wasted in the simulation (presumably on harmful mutations). Similarly, the reduction in the epoch count indicates that fewer successful species are created during the trial. Figure 2D, however, shows that the mutational distance covered by the runs *increases* with increasing randomness in the mutation networks: this demonstrates that although shorter, the runs with more random mutation schemes can produce more varied successful species.

## Summary & Conclusion

Taken together, the results shown here suggest that the optimal mutation strategy for the stringmol system is neither at  $p_{\text{reg}}$  or  $p_{\text{rand}}$ ; rather somewhere in between: in the small-world rewiring region. This work provides an experimental validation of the argument presented previously (Droop and Hickinbotham, 2011).

## Abstract

An essential feature of autonomous adaptive agency is that a system behaves according to an intrinsic norm. In this paper, we illustrate and clarify this notion of “behavior according to an intrinsic norm” with a minimalistic model of agency. We present a minimal metabolic system whose auto-catalytic dynamics define a viability region for different concentrations of available resource or ‘food’ molecules. We initially consider the availability of food as a control parameter for metabolic dynamics. A bifurcation diagram shows that for fixed values of available food, there exists a *viability region*. This region has a non-zero stable equilibrium and a lower boundary that takes the form of an unstable equilibrium—below which, the tendency of the system is towards “death”, a stable equilibrium with a zero concentration of metabolites. We define the viability region as that in which the system tends toward the “living” stable-equilibrium. Outside of this region, in the *precarious region*, the system may live for some time but will eventually die if the food concentration does not change. With a precise definition of system-determined death, living, precarious and viable regions we move on to reconsider the available concentration of resources ( $[F]$ ), not as a free parameter of the system but as modulated by organismic behaviour. By coupling the metabolism to a behavioural mechanism, we simulate a stochastic, up-resource gradient climbing behaviour. As a result, the effect of behaviour on the viability space can be mapped and quantified. This lets us move closer to defining adaptive action more precisely as that course of behaviour whose effect is in accordance with an intrinsic normative field.

## Introduction

The way in which living systems (from bacteria to humans) actively regulate their relationship with their environments strongly contrasts with inanimate objects. This *agency* is widespread in nature and it continues to capture the attention of philosophers, theoretical biologists, psychologists and roboticists alike, for it has proven to be a difficult property to define, model or synthesise.

The notion of agency often carries with it closely related and traditionally problematic notions such as normativity, adaptivity, individuality, teleology, intentionality, goal-directedness or free-will. Artificial life modelling techniques are well suited to provide a bottom-up approach ca-

pable of conceptually clarifying the systemic character of the properties associated with agency, its origins and nature.

After reviewing a wide variety of definitions and uses of the term ‘agency’ ranging from biology to robotics, Barandiaran et al. (2009) define agency as follows:

“an agent is an autonomous organization capable of adaptively regulating its coupling with the environment according to the norms established by its own viability conditions.” (p.376)

In this paper we attempt to make more explicit what is meant by the expression “according to the norms established by its own viability conditions”. Similar expressions have been used by Di Paolo (2005); Barandiaran and Moreno (2008); Skewes and Hooker (2009) but no model has yet been developed to illustrate and describe in detail the meaning of this expression (and others closely associated with it). The goal of this paper is to make progress in this direction using a minimalist model that can help understand and scientifically articulate a formal and quantitative definition of agency. To this end, we present a model that exemplifies the key concepts of “normative behaviour” in the context of agency. To further contextualize the model and its interpretation, in the next section we introduce the conceptual (i. e. philosophical) and theoretical problem and two contemporary approaches to it. We then introduce the design specifications of the model and analyze its dynamics and their interpretation in terms of normativity, precariousness, adaptivity and viability.

## Autonomous agency and normativity: some dynamic requirements

The issue of natural agency and norms is attracting increasing attention (Frankfurt, 1978; Burge, 2009; Di Paolo, 2005; Skewes and Hooker, 2009; Barandiaran et al., 2009; Silberstein and Chemero, 2011) and Artificial Life is very well suited to make some conceptual progress on key aspects of agency and its origins. In fact, minimal models of agency have been a recurring topic in the field (from protocellular models to robotics).

Figure 1: Classical picture of a Viability region defined for two essential variables (food and water), outside the region the system will die. Viable trajectories are those that remain within the boundaries of the viability region. Model generally focus on designing a control system that generates the appropriate trajectories inside the viability region but the region itself is given (e. g. arbitrarily designed or experimentally determined).

Arguably, minimal forms of agency (like chemotaxis) encapsulate some of the most important properties of “higher” levels of agency (such as human agency). One such property is *normativity*: i.e. the dimension of behaviour in which *value* comes into play—in which actions are good or bad, adaptive or maladaptive, appropriate or inappropriate (Christensen and Bickhard, 2002; Barandiaran and Moreno, 2008; Burge, 2009). While artificial systems can be judged to operate in relation to norms, these norms have (thus far) always been defined by the designer of the artificial system or interpreted by an external observer or user. In other words, what is good or bad functioning for a robot, a car or a coffee machine has been a matter of the design specifications which are largely independent of the structure and organization of the artifact. This is unlike biological organisms that respond to norms that are more closely related to the organization of the organism itself and what is (or is not) conducive to its ongoing operation.

Philosophers and scientists have tried to justify this normative dimension of natural agency in two ways. The most popular is the evolutionary (Millikan, 1989) approach in which a behaviour is considered to be normative or adaptive if it has been selected by evolution. In this view adaptation is ultimately a result of natural selection and it is only as a result of a process of selection that a character or process (e. g. a pattern of behaviour) can be said to be adaptive or maladaptive. This evolutionary approach to etiology, faces nu-

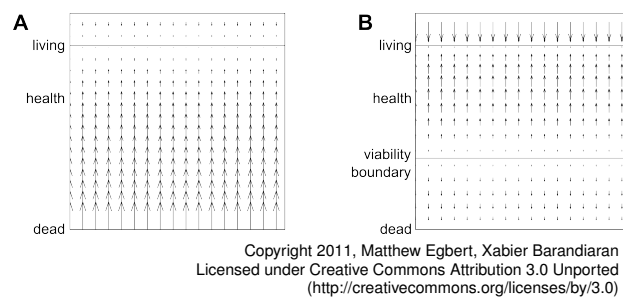

Figure 2: The viability boundary is an unstable equilibrium between living and dead states.

merous problems. One of them is how to categorise the first instance of a particular adaptive (i.e. norm following) behaviour? If a norm depends on an evolutionary selective history, then the first case of a “norm following” behaviour does not qualify as norm-following until it has been selected. This is clearly unsatisfactory. A criteria that is independent from history and is instead grounded on the very organization of the system and its ongoing dynamics seems better suited—indeed required—if we are to derive a consistent definition of adaptivity and normative behavior. This is precisely the motivation underlying the main alternative approach to normativity and adaptation. The *organizational approach* (as it might be called) puts at its center the idea of autonomy; from the Greek *autos* = self, and *nomos* = norm (Varela, 1979; Ruiz-Mirazo and Moreno, 2004; Di Paolo, 2004; Kauffman and Clayton, 2006). Although the origins of this approach can be traced back to the works of Aristotle and Kant (his *Critique of Judgement*), it was through the relatively modern development of theoretical biology and the physics and chemistry of far-from-equilibrium systems that it entered the scientific discourse. The contemporary conception of the organisational approach contends that norms are to be found as conditions of viability of the system, sometimes depicted in adaptive behaviour literature as a viability region (see Figure 1) or discussed as ‘viability constraints’ (Ashby, 1952; McFarland, 1999; Aubin et al., 2011). A closely related term is that of *precariousness* (Jonas, 1966, 1968; Weber and Varela, 2002; Di Paolo, 2005; Barandiaran et al., 2009), related, but not identical to the notion of “being far from thermodynamic equilibrium” when the system is a chemical or metabolic system (Ruiz-Mirazo and Moreno, 2004). The idea is that natural agents are organisms (i.e. living systems) that stand always in precarious conditions: if they don’t actively regulate their interaction with their environment (e.g. find food or a lower temperature) they will perish, since they exist in a continuous need of thermodynamic exchange with their environment. This precariousness is meant to form the basis of the normative character of behaviour: the system must actively seek to compensate its inherently decaying organization.

In a key paper where the theory of autonomy (in particu-

lar the autopoietic tradition) is complemented and expanded with Ashby's framework for adaptive behaviour, Di Paolo (2005) defined adaptivity (in relation to agency) as:

“a system's capacity, in some circumstances, to regulate its states and its relation to the environment with the result that, if the states are sufficiently close to the boundary of viability, 1. tendencies are distinguished and acted upon depending on whether the states will approach or recede from the boundary and, as a consequence, 2. tendencies of the first kind are moved closer to or transformed into tendencies of the second and so future states are prevented from reaching the boundary with an outward velocity.”

Di Paolo's definition of adaptive agency could be explicitly modelled and formalized. However, most of the models that have been developed with similar approaches have failed to address two blind spots: (1) viability boundaries appear as given or defined from without and the models focus on how to shape adaptive dynamics to maintain the trajectories of essential variables within those boundaries; (2) as a consequence, the relationship between the organismic dynamics that define the boundaries and the dynamics that control adaptive behaviour remain decoupled. In previous work (Egbert et al., 2009, 2010b) we have explored the relations between the viability boundary determining metabolic dynamics and the dynamics that drive organismic behaviour. A further problem remained however: although the boundaries of viability were directly linked to the modelled system, they were only defined by the system in a relatively trivial way. The boundaries of our models and similar efforts by others (see e.g. Ruiz-Mirazo and Mavelli, 2008) were the result of rough physical magnitudes: disappearance of the protocell due to complete lack of catalysts or bursting disintegration of the protocell marked by the upper limit of the tension of the membrane. The boundaries were not emergent from interactions between system processes in the holistic system-interdependent manner that characterizes integrity and systemic identity in real organism. In our previous models viability boundaries equated to absence of the system (i.e. total disintegration or zero quantity of its constituent elements). But, in natural systems, the limits of viability do not map with the physical disintegration of a system (Figure 2A), but rather with the loss of the capacity of the system to sustain itself. To lose viability is not to disappear altogether but to cross a much more subtle boundary after which the maintenance of life becomes impossible (Figure 2B). This boundary is the result of the dynamic organization of the system and, as we shall see, it defines a norm that behavioural patterns need to satisfy in order to be adaptive.

In this paper we model a minimal protocell-like system whose metabolic dynamics define an emergent viability boundary. For fixed concentrations of available resources, we can plot a bifurcation diagram of the chemodynamics

Figure 3: A) The influences of the forward and backwards flow of the autocatalytic reaction and degradation upon the concentration of A. B) The combined influence of the chemical reactions and degradation upon the concentration of A given a fixed concentration of  $[F] = 1.4$ .

that indicates the intrinsic boundaries of viability of the system. Different viability regions can be identified and the adaptive norms of the system clearly defined and quantified.

We then couple a gradient climbing behavioural mechanism to the metabolic dynamics. We show that in this metabolism-behaviour coupled system, the behaviour of the system can be directly mapped into the viability space of the simulated agent and it is possible to explicitly show and quantify how the system is adaptive for and by itself.

## Model

### Minimal metabolism

The metabolic organisation of self-production is one of the most fundamental properties of living systems and has been studied as such by many (Kauffman and Farmer, 1986; Kauffman, 2003; Varela, 1979; Ruiz-Mirazo and Moreno, 2004). In creating and maintaining themselves, living systems define their own viability constraints—the necessary and sufficient conditions for their continued existence. Thus, for the present work, metabolism is particularly relevant because it captures precisely what we wish to study. In its minimal and essential form it suffices to model metabolism as the self-production of a chemical network through the transformation (by the network) of available resources into constituents of the network. In previous work (Egbert et al., 2010a,b, 2009) we have modelled these kinds of systems in more detail, but here we abstract the system into two categories of components that we use to approximate a more

Figure 4: The system has a single stability at  $[A] = 0.0$  for low concentrations of  $F$ . At  $[F] \approx 1.1$  the system bifurcates, and for concentrations of  $F$  greater than this value, the system has two stable equilibria—the “living stable equilibrium” (where  $[A] > 0.0$ ) and “dead” (where  $[A] = 0.0$ ) and one unstable equilibrium, the viability boundary.

complicated metabolic system. These categories are ‘food’ or resource reactant(s) ‘ $F$ ’ and metabolites, i. e. members of the autocatalytic set, ‘ $A$ ’. Note that this approximation can be read as a higher order description of a more complicated system where  $A$  might capture an order parameter of a complex network of reactions among multiple molecules. In fact a recent and more complex model by Piedrafito et al. (2010) can be taken as dynamically similar to the present one, although it has a higher number of metabolites and catalysts and addresses other theoretically relevant properties (such as catalytic closure—which despite its relevance for the overall project of defining life and agency we have decided to leave aside for the specific purpose of the present paper).

We approximate the global dynamics of a more complex network according to the following reaction in which two members of the autocatalytic set interact with  $F$  to produce a third member of the autocatalytic set.

Note that the arrow is bidirectional, meaning that the reaction can occur in either direction, as is the case for all chemical reactions. A rate constant is associated with each direction (forward and backward) of the reaction  $k_b = 0.45$ ,  $k_f = 1.0$ . In addition to this autocatalytic reaction,  $A$  is subject to degradation into lower energy chemicals that are assumed to have no subsequent effect on the reaction and

are therefore not modelled. The combined influence of the forward and backward autocatalytic chemical reaction and the degradation are simulated by the following differential equation in which the degradation constant  $k_d = 1.0$ .

$$\dot{[A]} = \frac{-k_b[A]^3}{6} + \frac{k_f[F][A]^2}{2} - k_d[A]$$

## Metabolism-based chemotaxis

To study how behaviour can be sensitive to the viability boundary, we couple the metabolism to a simple stochastic gradient-climbing behavioural mechanism known as “run or tumble”. The run and tumble behaviour is inspired by the behaviour observed in *Escherichia coli* and other bacteria, that achieve chemotaxis through probabilistic modulation of two behaviours, “running” where the organism moves in a roughly straight line and “tumbling” where the organism chooses a new orientation at random. The mechanism modelled here is a form of *metabolism-based-chemotaxis*, meaning that no specific sensor nor chemical pathway is required to modulate behaviour; instead metabolism itself affects the behavioural probabilities so as to modulate the probability of tumbling (see Egbert et al., 2010b).

We have employed this coupling of metabolism and behaviour in previous papers to study the adaptability that such a coupling provides (Egbert et al., 2010b) and the possibility that an interaction between metabolism, behaviour and evolution can facilitate adaptive evolution of populations of protocells (Egbert et al., 2010a, 2011). Here we study how such a behavioural mechanism influences trajectories along the viability space.

In this case, the simulation of metabolism-based behaviour works as follows. The agent is considered to always be in a default state of running (moving in a straight line)  $\dot{x} = k\cos(\alpha)$ ,  $\dot{y} = k\sin(\alpha)$ . Tumbling occurs probabilistically with a likelihood that is modulated by the change in the concentration of  $A$ . If, since the previous iteration,  $[A]$  has decreased, the organism will tumble—i. e. a new orientation will be chosen from a flat distribution ( $\alpha = \text{rnd}[0..2\pi]$ ). Otherwise, the agent will continue running. A tumble inhibits any further tumbling for 5 iterations.

This particular form of metabolism-based run tumble mechanism is a highly simplified approximation of the “derivative” method used by *E. coli* and that simulated in (Egbert et al., 2010a, 2011) that compares the current metabolic rate to its rate a few moments previous. A decrease in metabolic rate indicates a worsening situation and increases the chance of a reorientation of the organism. In this way, the organism performs a simple but highly effective and surprisingly adaptive (Egbert et al., 2010b) behavioural strategy that can be captured by the anthropocentrism “If things are going well, I’ll keep going in this direction that I’ve been heading, otherwise, I’ll go somewhere else.”

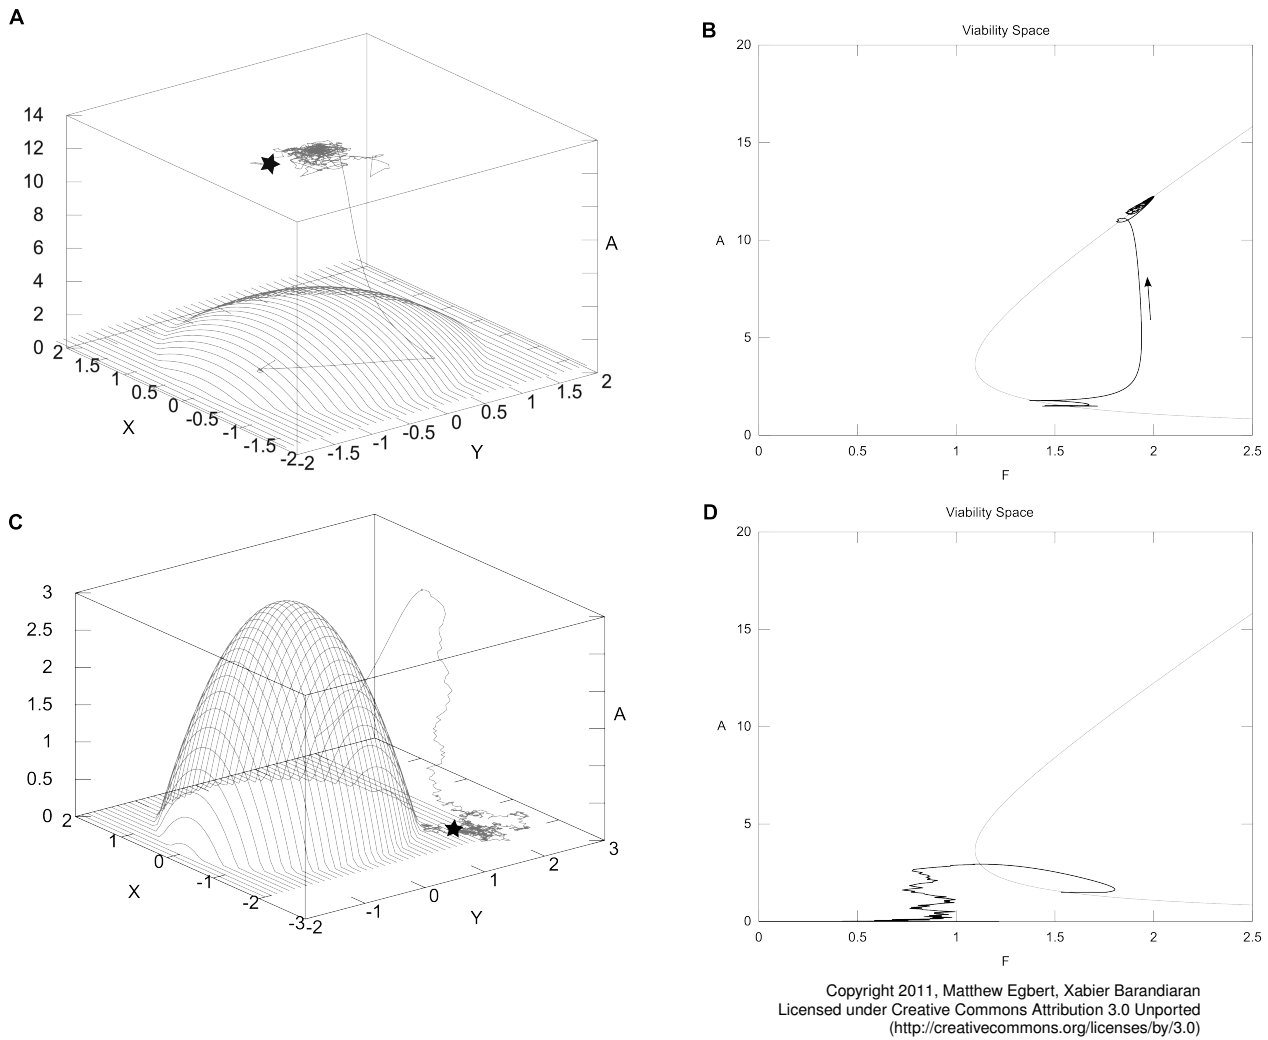

Figure 5: Paths taken by a successful chemotactic agent (top plots) and an unsuccessful agent (bottom plots). The left plots indicate the path of the agents in space plotted against  $[A]$ . The surface at the bottom of the image indicates the concentration of  $F$  in the environment. The right images show the path taken by the agents through viability space (see Figure 4). Initial oscillations around the viability boundary are eventually replaced by a trend up to the “living stable” equilibrium, thanks to the chemotactic motion.

## Simulation results: metabolic and behavioural dynamics

### Metabolic dynamics: bifurcation line as viability boundary

We first consider the metabolic system independently of behaviour and study its dynamic for fixed concentrations of  $F$ . Intuitively, it is clear that with no food,  $[F] = 0$ , the system should be unable to maintain itself in the face of degradation. This is also the case for low concentrations of  $F$ . As we start to increase  $[F]$  however, the combined effect of its progressive disintegration and the forward and backward metabolic reactions of  $A$  leads to a bistable dynamic regime. The dynamic tendency of the three reactions and their combined effect for a fixed value of  $[F] = 1.4$  can be seen in

Figure 3A. It is clear from Figure 3B that this system has two stable equilibria, “death” at  $[A] = 0.0$  and “living stable” at  $[A] \approx 7.5$ , with an unstable equilibrium, the viability boundary at  $[A] \approx 1.8$ .

Analysis of the metabolic dynamics for different, fixed values of  $[F]$  gives us the bifurcation diagram in Figure 4. For  $[F] > 1.1$ , there is enough food to maintain a non-zero concentration of  $A$ . In this area of the parameter space, the system has two stable equilibria: “living stable” (where  $A > 0.0$ ) and “dead” (where  $[A] = 0.0$ ) and one unstable equilibrium, the *viability boundary* (the dashed line in Figure 4). Below the viability boundary, the system tends towards the “dead” equilibrium.

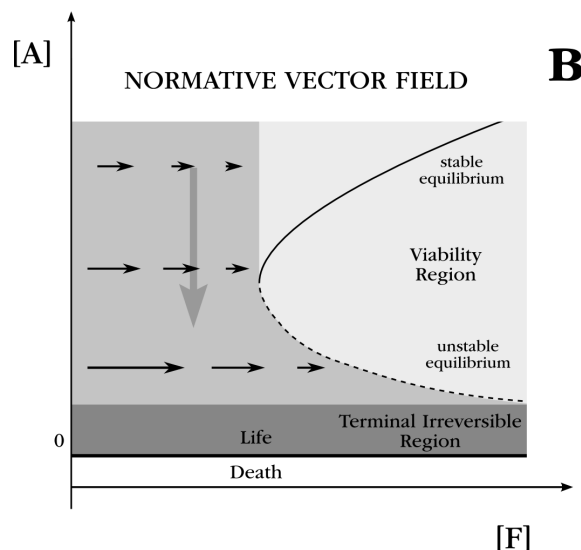

Figure 6: A summary of the regions of viability space: living, death, viable and precarious. See main text for further explanation.

### Chemotactic behaviour

Figure 5 shows the trajectories of two different agents using the metabolism-based mechanism. The left-hand figures shows motion in space plotted against  $[A]$ , the concentration of the autocatalyst. The right-hand figure shows the trajectory of the agent in “viability space” i.e. the same space as shown in the bifurcation diagram in Figure 4. The top images are for an agent that succeeded at performing chemotaxis. The lower images are the same, but for an agent that has had “bad luck” and the stochastic gradient climbing mechanism has failed.

### Model interpretation and discussion: Agency, precariousness, norms and adaptivity

This simple model suffices to satisfy a minimal requirement of normative behaviour, in that it generates a viability space where, living, viable, precarious, irreversible-terminal and death regions can be clearly identified. These are highlighted in Figure 6. The “dead region” can be clearly seen as the zero concentration of the required metabolites (a complete disintegration of the system). A *viable region* is identified where, given a fixed supply of resources, the system will maintain itself, growing or shrinking until it reaches the “living stable” equilibrium. The arrows indicate the tendency of metabolic dynamics for different regions of the viability space. The viable region can be precisely defined for a range of the parameter  $[F]$  and a range of initial conditions  $[A]$  as the subregion of the living space where for each point the evolution of the system will tend toward the stable living equilibrium. The unstable equilibrium at the bottom of the

 (<http://creativecommons.org/licenses/by/3.0>)

Figure 7: The idea of the ‘normative field’ in the precarious region – the effects of behaviour as efforts to move the system into the region of viability.

viable region defines a lower boundary of viability below which, the system tends toward death. For small values of  $[A]$  and  $[F]$  we can distinguish a *precarious* region (medium grey area in Figure 6), where the system is still alive but will tend to die if the parametric condition  $[F]$  is kept constant, but could still recover if  $[F]$  is appropriately modulated. Underneath the precarious region a terminal-irreversible region can also be distinguished (dark grey area in Figure 6). If  $[A]$  falls in this region the system will be “alive” for some time, but will irreversibly die (given a certain limit of  $[F]$  increase, defined e. g. by diffusion).

We can now introduce the notion of a *normative vector field* defined by the minimal constant increase of  $[F]$  that is required at each point of the precarious region in order to move the state of the system into the viable region before the system reaches the terminal-irreversible region. Figure 7 is meant to illustrate this field: if the values of  $[F]$  and  $[A]$  are low (bottom-left side of the figure) the required increase of  $[F]$  is very big since the tendency of  $[A]$  will soon push the system to the terminal-irreversible region. If the concentration of  $F$  is low but there is a lot of  $A$  the required constant increase in  $[F]$  is low because the system has sufficient time to reach the viability boundary before the tendency to die becomes irreversible. Since  $[F]$  can be modulated by behaviour (provided that the environment displays a gradient of  $[F]$ ) a sense of *normative agency* can be precisely defined for every state of the system in the precarious region: the amount of increase of  $[F]$  that behaviour should achieve to compensate for its precariousness, that is the required movement in space that increases available  $[F]$  in accordance with

Figure 8: The effect of agency, idealised in this figure, but also seen in Figure 5. See main text for further explanation.

the normative field. Note that the system can fail to meet the norm, i.e. to adapt, for a variety of causes (e.g. because there is not enough  $[F]$  in the environment, because it cannot move sufficiently fast or does not manage to move up the gradient —like the case of the experiment shown in Figure 5-bottom). And yet the action can be said to be in accordance with the norm if it positively correlates with the normative field.

Agency can thus be clearly defined as the behavioural modulation that positively correlates with the normative field (which shall, given the appropriate environmental conditions, bring the system to its viable region). Figure 8 illustrates this point. To further illustrate this idea we examined an agent with a “perfect” gradient climbing mechanism that always moves directly up-gradient with a constant velocity. (Removing stochasticity from the behaviour in the model makes some of the dynamics easier to visualize.) Figure 9 plots one such “perfect gradient climber” with the same initial values of  $[A]$  but different distances from the peak of  $F$  gradient. We can see how the agent repeatedly moves from the precarious region back into the viability region, except for very low values of  $[F]$  for which the system, despite its behavioural modulation of  $[F]$  fails to reach the viability region and perishes – as the behavioural mechanism is insufficient to compensate.

## Conclusions

To conclude, we state that *for autonomous agency* (that is agency in relation to self-generated norms) *to take place the overall global constitutive dynamics of the system* (its self-maintaining organizational dynamics) *should at least* (that

Figure 9: Trajectories of the system in the viability space as a function of its gradient climbing behaviour. Solid lines indicate trajectories that lead to the living stable equilibrium, dotted trajectories (despite behavioural influence) tend to death.

is minimally) *display an intrinsic topology with a viability boundary* (with the form of a bifurcation) *that defines a precarious region where behaviour can compensate for a death-ward tendency*. Arguably, it is only in relation to the intrinsically determined normative field that behaviour can be properly identified as adaptive and constitute a clear instance of natural normative agency.

The present model benefits from its low dimensionality in that it is easier to understand, but it also suffers, perhaps, from being over simplified in that there is really only two ways that the system can vary. Real organisms are of course much more complex and would display a multi-dimensional normative field and viability boundaries or surfaces. We are working on a more detailed model of a system similar to that described here in which the metabolism and behavioural mechanisms are more explicitly modelled (using more reactants and reactions). This will allow us to explore a greater variety of perturbations to system “health” as well as ways for the system to be sensitive (and therefore responsive) to its own viability. Another expansion of this work that we are considering is the quantification of a normative vector field and the formalization of the notion of positive correlation with it.

## Abstract

This paper describes research in which we model social interactions between artificial agents using real robots. We show that variations that arise from embodiment allow certain behaviours, those that are more robust to the processes of embodied imitation, to emerge and evolve during multiple cycles of imitation. We test 3 memory strategies: no memory, limited memory and unlimited memory, and experimental results appear to show that with limited memory, those behaviours are more likely to become dominant within the robots' collective memory.

## Introduction

Social learning, which enables individuals to learn from each other, is a powerful mechanism in social animals, including humans. An important form of social learning is imitation, in which an individual observes and replicates another's actions. Imitation has been widely studied both by biologists and psychologists; biological research on imitation mostly focusses on its adaptive value for the organism, whereas psychologists are largely interested in the function of imitation and the mechanisms in which it plays a part (Zentall, 2001). There is continuing debate on the definition of imitation and whether it is unique to humans but what is not in doubt is that imitation clearly serves an important role in the development of social cognition in humans. For example, Dautenhahn et al reported that human babies are born with the ability to imitate a wide range of behaviours, including mouth opening and tongue protrusion (Dautenhahn et al., 2003). Meltzoff and Moore (Meltzoff and Moore, 1992) stated that human infants use imitation to enrich their understanding of people and their activities. Through imitation, humans are able to become part of a very complex social environment: human society. Imitation has also been seen as an important facet of cultural transmission; Dawkins argued (Dawkins, 1976) that imitation is a prerequisite for the evolution of culture, as it allows transmission of behaviours, with variation, between individuals.

The study of imitation in robotics has received cross-disciplinary attention in recent years. In the context of

robotics research, Bakker and Kuniyoshi (Bakker and Kuniyoshi, 1996) defined imitation thus: "Imitation takes place when an agent learns a behaviour from observing the execution of that behaviour by a teacher". This definition hints at how imitation is implemented and is used in most robotics research. Skill acquisition by human or robot demonstration has been widely investigated ((Scassellati, 1999); (Mataric, 2000)). This approach holds the promise that we may be able to overcome the necessity to program every behaviour a robot may need to perform, as the robot can learn new behaviours through observing demonstrations of those behaviours. However, as stated above, as well as supporting skill transmission between individuals, in human society, imitation has a social dimension, allowing individuals to become part of a social community. Alissandrakis et al. (Alissandrakis et al., 2004) stated that imitation may serve as a stepping stone towards the development of social cognition in artificial agents as it can form social integration with other artificial agents or with humans. Imitation research in robotics might also usefully address the question of how culture emerges and evolves as a novel property in groups of social animals. In (Winfield and Erbas, 2011) we introduce embodied imitation as a method for modelling the emergence of behavioural 'traditions' in social agents.

There has been some work examining the social dimension of imitation in robotics. Steels and Kaplan (Steels and Kaplan, 2001) stated that social learning can play a crucial role in initiating a humanoid robot into a linguistic culture. He used methods such as initiating open-ended dialogues among humans and robotic agents, in which social learning could be embedded. Billard (Billard, 1999) claimed that imitation can be used to enhance autonomous robots' learning of communication skills. The sharing of a similar perceptual context between the imitator and demonstrator can create the necessary social context in which language can develop. Billard devised some experiments in which robotic agents were able to learn a proto-language by using imitation to match their environmental perceptions with observed actions. In this paper, we aim to show that by sharing a similar perceptual context, agents involved in multiple cycles of imitation

can – in a sense – agree on the structure of the information that can best be transferred by imitation (that is, what can be imitated). Multiple robots are programmed to observe and imitate each other's movement patterns and the imitated behaviours undergo multiple cycles of copying, in which they mutate because of noise and uncertainties in the real robots' sensors and actuators. We observe that some movement patterns, which can be imitated with high fidelity, emerge and evolve in the group of real robots.

Alisandrakis et al. (Alisandrakis et al., 2004) developed the ALICE architecture (Action Learning via Imitation between Corresponding Embodiments) to address the problem of imitation between dissimilar embodiments. They examined the rules of synchronisation, looseness of perceptual matching and proprioceptive matching in a series of experiments in which robotic arms with variably-sized and numbered joints imitate each other. They showed that patterns can be transmitted between simulated robotic arms and variations occur during these replications because of heterogeneities between the arms. They argue that these variations provide the evolutionary substrate for culture, as new behavioural patterns may emerge and be transferred between agents. In this paper, we describe a series of experiments in which real robots observe and imitate each other's movement patterns. We show that even in an homogeneous group of real robots, variations occur during the imitation process that allow certain behavioural patterns to emerge and evolve during multiple cycles of imitation. These evolved behaviours can be copied with higher fidelity, as they are more robust to uncertainties in the real robots' sensors and actuators.

### Imitation in Robots

As stated above, we have used real robots to model the social interactions between agents. The motivation for using real robots rather than simulated agents or biological social entities for modelling is:

- Real robots, with their less than perfect perception and actuators, provide natural variations in the imitation process which allow new behaviours to emerge and evolve. Using simulated agents in a simulated environment, we would have to control the degree and types of heterogeneities and noise, but this may preclude any emergent processes that are a part of imitation; the level of emergence in a simulated environment would be limited to the level of variance that is artificially introduced.
- Data about the imitative activity, including the internal data and calculations of the robots, can easily be extracted and examined. This would not be the case if biological social entities (for example, people or monkeys) were used.
- The implementation of imitation on real hardware makes clear how theoretical assumptions and hypotheses regarding imitation can be operationalised.

Figure 1: A Linux-extended e-puck robot. The robots are fitted with coloured skirts, to enable them to 'see' each other. The yellow hat on top of the robot provides a matrix of pins holding unique patterns of reflective markers that allow the tracking system to identify and track each robot.

### Hardware Setup

The artificial agents used to model social interactions are *e-puck* miniature robots (Mondada et al., 2009), 7 cm in diameter and 5 cm in height. They are equipped with 2 stepper motors, two wheels of 41 mm diameter, 8 proximity sensors, a CMOS image sensor, an accelerometer, a microphone, a speaker and a ring of coloured LEDs. Their on-board battery provides 3 hours of autonomy. The robots are enhanced with a Linux extension board (Liu and Winfield, 2011) based on the 32-bit ARM9 micro-controller with the Debian/Linux system installed. The board has a USB extension port, used to connect a wireless network card, and is equipped with a MicroSD card slot. These additions to the standard e-puck robot offer increased processing power and increased memory. The robots are also fitted with coloured 'skirts' to enable them to see each other using their built-in image sensors. The experiments are performed in an arena measuring 3 m x 3 m. A vision-tracking system provides high-precision position tracking and a dedicated swarm server combines the data from the tracking system and the internal data from robots for later analysis. Each robot is also fitted with a tracking 'hat' which provides a matrix of pins holding unique patterns of reflective markers that allow the tracking system to uniquely identify and track each robot (Fig. 1).

### Movement Imitation Algorithm

In this research, a robot-to-robot movement imitation algorithm is implemented on the Linux extended e-puck robots.

Each robot is able to track and copy the other robot's movement patterns. Since we are interested in embodied imitation, the algorithm completely depends on the visual data coming from the image sensor of the robots; no other type of communication is allowed between the robots.

There are 3 main stages in the imitation algorithm:

- **Frame processing:** While observing captured visual frames, the observing robot tracks the movement of the demonstrator robot. As stated above, the robots are fitted with coloured skirts; by determining the size and location of the skirt on the demonstrator robot, the observing robot estimates the relative position of the demonstrator and stores this information in a linked list of positions. In this way, up to 5 frames per second are processed.
- **Data processing:** After the demonstrator's movement pattern is completed, the observer robot processes the linked list of positions using a regression line-fitting method to convert the estimated positions into straight line segments.
- **Pattern replication:** The straight line segments and their intersections are converted into a sequence of motor commands (moves and turns).

In this way, the observing robot replicates the pattern demonstrated by the demonstrator robot.

### Quality of Imitation

To quantitatively assess the fidelity of imitation (that is, the similarity between the original movement pattern and its copy), a quality of imitation function needs to be defined. Since each movement pattern consists of straight moves and turns, there are 3 components to each pattern that can be copied: the number of segments (straight moves), the length of each move and the angle (turn) between each consecutive move. Therefore, the overall quality of a copy can be calculated by separately estimating 3 quality indicators. The quality of move length,  $Q_l$ , between the original path  $O$  and its copy  $C$  is calculated as follows:

$$Q_l = 1 - \frac{\sum_m |l_m^O - l_m^C|}{\sum_m l_m^C} \quad (1)$$

where  $l_m$  is the length of move  $m$  that is to be compared. Here, the ratio is calculated of move length differences between the original pattern and its copy and the total move length of the copy. If the original movement pattern and its copy have different numbers of segments,  $N^O$  and  $N^C$  respectively, the sum is calculated only over the number of segments in the smaller:  $\min(N^O, N^C)$ . The quality of angle (turn) imitation similarly calculated as:

$$Q_a = 1 - \frac{\sum_m |a_m^O - a_m^C|}{\sum_m a_m^O} \quad (2)$$

where  $a_m$  is the turn angle following the move  $m$ . The quality of segment imitation simply compares the difference between the number of segments of the original pattern and its copy. It is calculated as:

$$Q_s = 1 - \frac{|N^C - N^O|}{N^O} \quad (3)$$

where  $N^O$  and  $N^C$  are the number of segments of the original path and its copy. The overall quality of imitation,  $Q_i$ , is a combination of 3 quality indicators:

$$Q_i = \frac{LQ_l + AQ_a + SQ_s}{L + A + S} \quad (4)$$

where  $L$ ,  $A$  and  $S$  are weighting coefficients.

To test the quality of imitation, a demonstrator robot is programmed to follow a sequence of straight line moves and turns that describes an equilateral triangle, while an imitator robot watches. Then, the imitator robot performs its copy of the demonstrator's pattern (Fig. 2). By comparing these two patterns, the quality of imitation is determined. The same scenario is repeated multiple times, with different distances between the robots. As shown in the figure, the best quality is achieved when the distance between robots is 1 m (Fig. 3). When the distance between robots is increased (to 1.5 m or more) the quality of imitation starts to degrade. This arises because the relative positional changes are estimated based on the size and location of the observed robot in the field of vision of the imitator robot. When the separation distance increases, the positional changes are harder to detect, as they cause smaller variations in the image of the observed robot. On the other hand, when the distance between robots is small (that is, 0.5 m or less), the demonstrator robot leaves the field of vision of the imitator robot many times, forcing the imitator robot to rotate itself each time and thus it may miss some turns of the demonstrator robot's trajectory while it is busy. Therefore, we have a separation range, between 0.5 m and 1 m, that is optimal for our vision based embodied imitation algorithm.

### Experiments

The notion of an imitation experiment is introduced to examine the effects of multiple cycles of imitation on the structure of the movement patterns that are being copied. During these experiments, 4 robots are placed in the arena, 1 m apart from each other (Fig. 4). Robots interact by copying each others' movement patterns using the imitation algorithm outlined in the previous section. Robots can be in one of two modes during the experiments: demonstrator or observer. When a robot enters demonstrator mode, it turns its LEDs on for 35 seconds to signal that it will start to demonstrate a movement pattern. During this period the demonstrator tries to grab the attention of one (or more) other robots. After that, the demonstrator robot turns its LEDs off and executes a movement pattern that consists

Figure 2: Plot of the trajectory of robots during an imitation run. The demonstrator robot moved in an equilateral triangular trajectory which was then copied by the observer robot. The robots were placed 1m apart.

of straight-line moves and turns. When execution is complete, the demonstrator robot blinks its LEDs for one second to signal ‘finish’. Then the demonstrator robot returns to its original start position and enters the observer mode. When a robot enters observer mode, it searches for a start signal by scanning the arena while rotating itself. When it detects a start signal, it focuses its attention on the demonstrator robot and waits for the demonstration to start. After completion of the demonstration, the observer robot records what it has observed and enters demonstrator mode. The finite state machine of the controller of the robots is shown in Fig. 5. At the start of the experiment, two of the robots are in demonstrator mode (Robots A and B) while the other two are in observer mode (Robots C and D). The experiment is left free-running as the robots change roles while imitating each other. All internal calculations and movement patterns of the robots are recorded for later analysis.

### Imitation with no memory

In the first set of experiments, the robots are able to remember only the most recent pattern they have observed; any newly-observed pattern replaces the previous one. Robot A is initialised with a square trajectory and Robot B is initialised with an equilateral triangle trajectory. Fig. 6 shows the pattern evolution map of an experiment in which 39 successful imitations were completed in approximately 20 minutes. In the figure, each node represents a pattern. If an arrow exists at a node, this means one of the robots executed that pattern and it was imitated by another robot. The new copy is at the end of the arrow. If the copy is high-quality, ( $Q_i \geq 0.85$ ) the node has a dark colour.

We first observe in this experiment that the original patterns deteriorate very quickly. At the beginning of the run, both robots (C and D), by chance, copied the square trajec-

Figure 3: Mean quality of imitation ( $Q_i$ ) value with 95% confidence intervals calculated at different distances between robots. Each bar shows mean quality value over 20 cycles of imitation in which an equilateral triangle (each side 15 cm) movement pattern described by the demonstrator robot is copied by an imitator robot. For quality of imitation calculation, each quality indicator was given equal weight:  $L = A = S = 1$ .

tory and the triangular trajectory vanished from the experiment. The square trajectory also deteriorates rapidly, as any low quality copy can easily replace it. Because some bad copies missed turns, eventually the robots ended up with a pattern consisting of a single forward move. These low quality copies do not occur often but just one is sufficient to disrupt the evolution of the movement patterns. In this experimental run, all patterns after pattern number 22 consist of one single move without any turns. These single move patterns can be copied with high quality but we still observe some poor copies. We conclude therefore that when robots have no memory, evolution of the movement patterns is acutely sensitive to imitation errors.

### Imitation with unlimited memory

In the second set of experiments robots have unlimited memory so they save all patterns that they have observed. When they enter demonstrator mode robots randomly select, with equal probability, one of the patterns in their memory and demonstrate it. Once again Robots A and D are initialised with a square trajectory and Robots B and C are initialised with an equilateral triangle trajectory. Fig. 7 shows the pattern evolution map for an experiment with this setting. In this run, 55 successful imitations were completed in 30 minutes. We first observe in these experiments that – as we would expect – the original movement patterns are more likely to be preserved (with variation), as each newly-observed pattern is stored in memory. Low quality copies occasionally occur, but as they do not replace previously ob-

Figure 4: Each experiment presented in this section is performed in a 3 m by 3 m arena with 4 robots, placed 1 m apart and arranged as shown here. In all experiments, Robot A and Robot B are started in demonstrator mode while Robot C and Robot D are started in observer mode.

served patterns, these paths cannot easily become dominant. Second, we see that as patterns evolve during multiple cycles of imitation, some paths that are able to be copied with high quality emerge and propagate among robots. In this run, pattern 27 has this property. Fig. 8 shows the evolution of pattern 27. It is a descendant of the original equilateral triangle trajectory, and there are 5 intermediate copies between the original triangle and pattern 27. At each copy, the pattern is modified by the imitating robot. Finally pattern 27 emerges and a sharp increase in quality of imitation can be observed after this point ( $Q_i > 0.94$  for all of its descendants). What makes this pattern and its descendants easily copiable? First, short moves are more prone to error, as a small mistake in perception can cause them to vanish; a pattern that can be copied with high quality typically does not include short moves. Second, the length of each move varies at each subsequent copy. Although estimating the relative size and position of the demonstrator robot is straightforward image processing, it is error-prone, because of the relatively low resolution of each robot’s image sensor. A move directed towards or away from the observing robot can only be detected if it causes a perceptible change in the size of the demonstrator robot, i.e. a detectable change in number of pixels in the image of the demonstrator. At each copy, the observing robot stores what it infers from the demonstration, as perceived from its relative position and perspective. Therefore, the patterns tend to evolve into ones that can be more easily imitated. Fig. 9 shows pattern 27 and its descendants. As can be seen, there is a high level of similarity between these patterns. At the end of the run, pattern 27 and its descendants form a cluster of similarly-shaped patterns in the robots’ memories. Fig. 10 shows the average  $Q_i$  value for this experiment in comparison with the average  $Q_i$  value for the cluster formed by pattern 27’s descendants. As can be seen, although the distance between the robots is 1 m, the

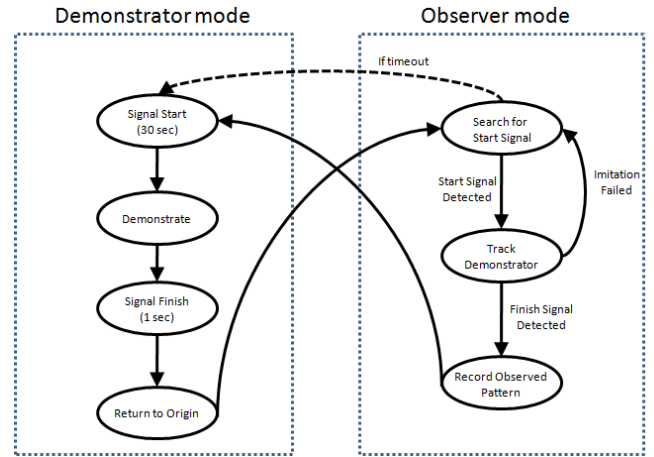

Figure 5: Finite state machine of the controller of the robots. The robots are programmed to copy each others’ movement trajectory as they keep changing their roles to demonstrator and observer. To prevent a deadlock with all the robots searching for a start signal, two of the robots (Robot A and Robot B) are programmed to time out and enter ‘Signal Start’ state after completing two complete scans of the arena in ‘Search for Start Signal’ state (the dashed arrow).

average  $Q_i$  value is slightly low; around 0.83. This can be explained by the fact that some low quality imitations occur during the evolution of patterns. A sharp increase in  $Q_i$  value can be observed after a pattern emerges that is more robust to uncertainties in the robot’s sensors and the imitation process: the average  $Q_i$  value for the cluster that is formed by the descendants of pattern 27 is 0.96.

### Imitation with Limited Memory

In the previous set of experiments, we showed that certain patterns, those that are more robust to uncertainties in the real robots’ sensors and actuators and the estimation process of imitation, can emerge and evolve during multiple cycles of imitation. As these emergent patterns can be copied with high quality, their descendants have similar, inherited characteristics. As a result, clusters of highly copiable patterns are formed in the memories of the robots. These clusters may grow larger with subsequent cycles of imitation if, by chance, members of these clusters are selected for demonstration. We now show that with a limited memory, these emergent patterns and their copies can become dominant. In the third set of experiments, an example run with limited memory is presented, in which an emergent pattern and its highly similar descendants become dominant. Here robots have a limited memory, in which they can store only the most recent 5 patterns observed. When the memory is full and a new pattern observed, the oldest pattern in memory is replaced with the new pattern. Fig. 11 shows the pat-

Figure 6: Pattern evolution map for a 4 robot experiment with no memory. Each node in the figure represents the demonstration of a movement pattern. If a pattern is demonstrated and imitated, the new copy of that pattern is linked to it by an arrow. For instance, pattern 2, the original square, was demonstrated by Robot A and was copied by two robots. The new (child) copies of pattern 2 are patterns 3 and 4. If the copy is of high quality (i.e.  $Q_i \geq 0.85$ ), then the node has a dark colour.

Figure 7: Pattern evolution map for a 4 robot experiment with unlimited memory. Initial movement patterns are a triangle (1) and a square (2).

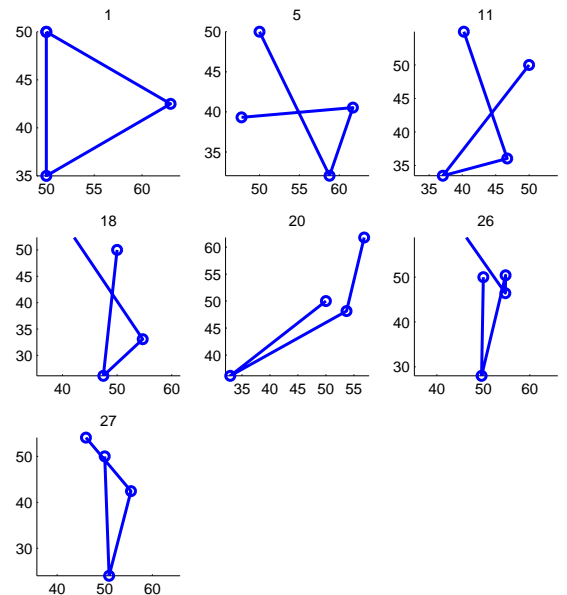

Figure 8: Evolution of pattern 27 in Fig. 7. Pattern 27 is a descendant of the original equilateral triangle pattern. By following the imitation links on the pattern evolution map for this experiment, we can see that there are 5 intermediate copies between the original triangle and pattern 27: the patterns numbered 5, 11, 18, 20, 26. All of these patterns, starting with the original triangle and ending with pattern 27, are shown here in order. All axis are marked in cm.

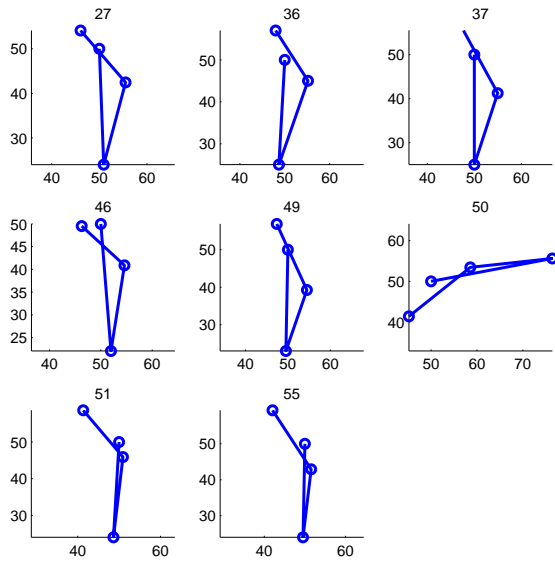

Figure 9: The descendants of pattern 27 in Fig. 7. Starting with pattern 27, its descendants (patterns 27, 36, 37, 46, 49, 50, 51, 55) are shown in order. All axes are marked in cm.

Figure 10: Average  $Q_i$  value for all imitation events in the experiment shown in Fig. 7 (All copies) and average  $Q_i$  value for the cluster formed by pattern 27’s descendants (Cluster), with 95% confidence intervals

Figure 11: Pattern evolution map for experiment with limited memory. The 20 patterns in the memory of all 4 robots at the end of the experiment are highlighted as diamonds.

Figure 12: Evolution of pattern 12 in Fig. 11. There is an intermediate copy (10) between the original triangle and pattern 12. All axes are marked in cm.

tern evolution map from an experiment with these settings in which 72 successful imitations were completed in 60 minutes. In this run, a V-shaped pattern, pattern 12, emerged and all of its descendants are high quality copies. Fig. 12 shows the evolution of this path and Fig. 13 shows some of its high-quality descendants. At the end of this run, 12 of the 20 patterns in the memory of all 4 robots are descendants of this pattern. Since the robots randomly choose which pattern to demonstrate, there is now a 60% chance that one of the descendants of pattern 12 will be demonstrated again. Once it is selected and copied, the new copy is itself likely to be a high quality copy and so similar to pattern 12. This process will then increase the percentage of patterns in the memory that are similar to pattern 12. We conclude therefore that with limited memory, patterns robust to uncertainties that emerge are more likely to become dominant.

### Conclusion and Discussion

In this work, we have used real robots to model social interactions between artificial agents, in particular learning by imitation. We have shown that variations in the real robots’ sensors allow certain behaviours to emerge and evolve during multiple cycles of imitation. These evolved movement

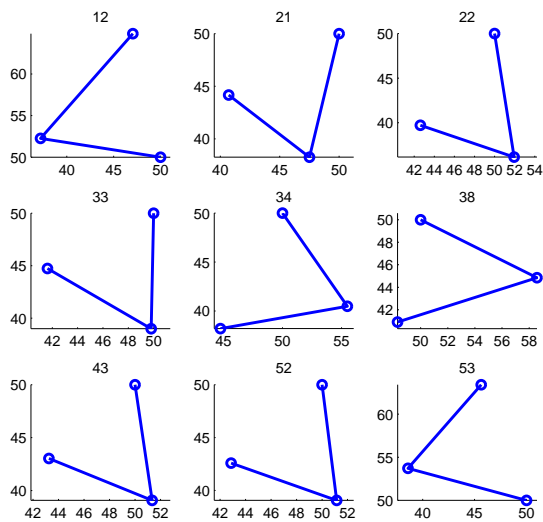

Figure 13: The descendants of pattern 12 in Fig. 11. Starting with pattern 12, some of its high-quality copy descendants (patterns 12, 21, 22, 33, 34, 38, 43, 52, 53) are shown in order. All axes are marked in cm.

patterns are more robust to the uncertainties of the real robot embodied imitation process and so they can be imitated with high fidelity. As the robots share a similar perceptual context and embodiment, they are able to – in effect – agree on the structure of the movement patterns that can be transferred between them.

We have experimentally tested three cases with different sizes of robot memories: no memory, unlimited memory and limited memory, in order to test the hypothesis that memory size will effect the likelihood of dominant movement patterns emerging. In the no memory case, the evolution of movement patterns is extremely sensitive to any instance of poor quality imitation, which means that the original movement patterns very quickly deteriorate. In the unlimited memory case, patterns emerge that can be easily copied but are less likely to then become dominant, as the number of patterns in the robots’ collective memory grows larger with each new imitation cycle. However, in the case with limited memory, these evolved patterns can become dominant if they and their descendants are, by chance, chosen for demonstration. For simplicity of analysis, we have carried out our limited memory experiments with a small memory size (5 patterns per robot). We conjecture that with a larger (but still limited) memory, multiple patterns that can be imitated with high fidelity can emerge and form clusters of similarly-shaped patterns in the robots’ collective memory. In this way, the robots can collectively evolve an ensemble of patterns that can be copied between them with high fidelity. Here the imitated patterns are not linked to a task or

an environmental context. However it seems possible, and testable using the embodied approach outlined in the paper, that associating imitation with behaviours that have utility could lead to the emergence of non-verbal communication between robots.

## Abstract

In most theories concerning the origin of life autocatalytic sets are supposed to play an important role in the phase transition between non-living and living matter. Although several theoretical models describe this phase transition, it is very hard to recreate the experimental conditions in wet lab. We here introduce a stochastic model of catalytic reaction networks with energy constraints, devoted to the study of the emergence of autocatalytic sets, in which some of the assumptions of the already existing model are relaxed in order to explore the possible reasons which make the emergence of autocatalytic cycles difficult or which make them unstable. Moreover, since living systems operate with a continuous exchange of matter and energy with the environment, we investigate the effects on the model behavior of changes in the rate of the energy intake.

## Introduction

The life as we know today is the result of billions of years of evolution and, even though the first forms of life were simpler than today, a certain degree of complexity was surely necessary in order to lead off the phase transition between non-living and living matter.

Although different scenarios for the onset of life have been proposed<sup>1</sup>, autocatalytic sets of molecules (ACSs) are considered of paramount importance to both extant biological systems and during the transition from non-living to living systems.

In the first case, ACSs represent the basic architecture of some of the most fundamental metabolic processes such as the citric acid cycle urea cycle, calvin cycle and beta-oxidation (Alberts et al., 2005), on the other hand, the

emergence of ACSs might have played a pivotal role in acquiring autonomy and homeostasis during the emergence of the first living systems (Ruiz-Mirazo and Mavelli, 2008) and they have been regarded ever since as the blueprint of primeval living systems (Fishkis, 2007; Ma et al., 2010).

Though the RNA world scenario, with particular regard to the role of the ribozymes (Gilbert, 1986; Talini et al., 2009), provides a plausible solution with respect to the prebiotic storage and replication of the information, it has been proven that template-dependent polymerization can occur only for relatively short nucleotides strands catalyzed by remarkably long RNAs (Bartel and Unrau, 1999; Bartel, 1999).

On the other hand, looking at the metabolism-first approach, the self-replication of only a single catalyst is plausible only within a very complex chemical system.

In his theory concerning the emergence of ordered structures and patterns of activation from disordered interactions (the so called “order for free” hypothesis (Kauffman, 1993)) Stuart Kauffman pointed out the idea that all that is needed is the presence of a set of molecules composed of a sufficient number of different molecular types in which each molecule catalyzes a step in the formation of one or more other molecules in the set; then the catalytic closure is reached if each molecule in the set is catalyzed by at least one other molecule of the set. Based on a combinatorial approach, Kauffman stated that the emergence of autocatalytic sets is inevitable when the molecular diversity reaches a certain threshold (Kauffman, 1986).

While the Kauffman initial approach is based on an analysis of the reaction graph, without taking into account the dynamics, there are several models in the literature that study autocatalytic systems from a dynamical point of view, such as those by Dyson (Dyson, 1985), Eigen and Schuster (Eigen and Schuster, 1977), Kauffman (Kauffman, 1986), Farmer and Bagley (Bagley and Farmer, 1992; Bagley et al., 1989), Jain and Khriشنا (Jain and Krishna, 1998), Lancet (Segre et al., 1998) and Kaneko (Kaneko,

<sup>1</sup>The main theoretical frameworks can be divided in the “gene first” approach, based on the template matching (Gilbert, 1986; Müller, 2006; De Lucrezia et al., 2007; Anastasi et al., 2007; Talini et al., 2009; Rios and Tor, 2009; Budin and Szostak, 2010), the “metabolism first” approach, based on the self-organization of the chemicals involved in (Oparin, 1924; Miller, 1953; Eigen and Schuster, 1977; Kauffman, 1986; Mossel and Steel, 2005; Lee et al., 1996; Saghatelian et al., 2001; Lifson, 1997) and the lipid-world (Segre et al., 1998)

2006).

Even if all these models predict the emergence of an autocatalytic set, observing it in a wet lab experiment remains a very difficult task. On the one hand, it is possible that the simplifications introduced by the in-silico models are unrealistic with respect to the extant biological systems but, on the other hand, the indications provided by the theory may be not correctly implemented in actual experiments.

In previous works (Fuchslin et al., 2010; Filisetti et al., 2011a,b, 2010) we introduced a novel stochastic model devoted to the study of the generic proprieties of catalytic reaction networks based on a particle description of the system, while in the present work we investigate the effects of the introduction of energetic constraints in the system.

Living systems cannot operate isolated from the environment and they need a continuous flow of energy and matter in order to be maintained far from the equilibrium. While the incoming flux of matter is necessary in order to feed the system with the elementary nutrients to be transformed in more complex molecules, energy is channeled into the construction of molecules whose constitutive reactions are energetically unfavorable. Energy is stored as chemical bonds in molecules called “carrier molecules”, which diffuse rapidly in the cell and thereby carry energy from places of energy generation to the reactions requiring energy to occur (Alberts et al., 2005).

While results concerning the influence of different composition of the incoming flux of matter have been presented in (Filisetti et al., 2010; Fuchslin et al., 2010; Filisetti et al., 2011a,b), here we focus on the role of the energy, some first indications can be found in (Fuchslin et al., 2010), within a system composed of both energetically unfavorable and favorable reactions.

It is important to remark that, coherently with the scientific approach typical of complex systems biology (Kaneko, 2006), we are not interested in investigating the specific nature of the chemicals present in our model, nor the particular interactions among them, but rather in the characterization of the dynamical behaviors emerging from the interaction of a set of chemicals and in the detection of possible generic properties of this kind of systems.

In section II the principal features of the models are presented while in section III we describe how the energy has been introduced in the stochastic model. In section IV we discuss some preliminary results of a set of simulations in which we study the influence of the amount of energy introduced in the system and, in the final section, conclusions and indications for further works are provided.

## Description of the model

An exhaustive description of the model can be found in (Filisetti et al., 2011a) and (Filisetti et al., 2010); we here summarize the principal features for a better comprehension of the paper.

Taking inspiration from the original work by Kauffman (Kauffman, 1986) the principal entities of the model are linear chains, species from now on, oriented from left to right, composed of the concatenation of letters from a finite alphabet, e.g.  $[A,B]$  or  $[A,G,C,T]$ .

Let  $X$  stands for the entire set of species and  $x_i, i = 1, \dots, N$ , representing each single species. In accordance with the stochastic nature of the model the total amount (quantity of *molecules*) of each species  $x_i$  is denoted by  $\hat{x}_i$ . Since the reactions take place in a well-stirred tank reactor with fixed volume, the relation between concentrations and quantities is straightforward.

The dynamics of the system is ruled by two different reactions, namely *condensation* and *cleavage*. By means of the former two species are concatenated in order to create a longer species (e.g.  $AB + BA \rightarrow ABBA$ ), whereas by means of the latter one specie is cut in order to create two shorter species (e.g.  $ABBA \rightarrow AB + BA$  or  $ABB + A$  or  $A + BBA$ ), in general given a species of length  $l$  there are  $2(l - 1)$  different cleavage products.

We assume that for spontaneous reactions the rate of the backward reactions is negligible with respect to that of the forward reactions (i.e. strongly negative  $\Delta G^\circ$ ).

Furthermore, since we are interested in the behaviors of catalytic reaction networks we assume that no reaction proceeds without the aid of catalysts, namely all reactions are characterized by a high energy barrier (i.e. activation energy) that would make them too slow to be observed in the absence of the correspondent catalysts.

The main novelty presented in this work is the explicit introduction of energy constraints, according to which some types of reaction require energy to proceed, as it will be described in the following section.

It is important to notice that the present version of the model neglects any catalysis provided by elements other than species belonging to the system, even though environmental catalysts, such as mineral clay, are thought to have played a relevant role in prebiotic synthesis (Ferris et al., 1996).

Given the number and the length of the species present in the system one can compute the overall number of conceivable reactions, including both cleavage and condensation, as

$$\hat{R} = \sum_{i=1}^N (L(x_i) - 1) + N^2. \quad (1)$$

where  $L(x_i)$  is the length of the  $i$ -th species and  $N$  is the

total number of species present in the system. An important assumption is that we consider an independent probability  $p$  that any species catalyses a random reaction, hence not all the  $\hat{R}$  conceivable reactions will occur, but only those that are actually catalyzed by some of the existing species.  $p$  turns out to be one of the key parameters of the model, since it rules the overall activity of the system by tuning the number of possible catalysts present in the reactor.

The dynamics is based on the well-known Gillespie stochastic algorithm (Gillespie, 1977, 2007) but, in order to speed up the computational performance, some of the processes are described by means of an approximated algorithm; in particular the ingoing and outgoing fluxes and, as we will see in the next section, the dynamics related to the introduction of the energy.

In accordance with the nature of the reactions, i.e. condensation and cleavage, we can summarize the reaction scheme as following:

- Cleavage:  $AB + C \rightarrow A + B + C$
- Condensation: (whole reaction:  $A + B + C \rightarrow AB + C$ )
  - Complex formation:  $A + C \rightarrow A : C$
  - Complex dissociation:  $A : C \rightarrow A + C$
  - Final Condensation:  $A : C + B \rightarrow AB + C$

where  $A$  and  $B$  are two generic substrates involved in a specific reaction,  $C$  is the specific catalyst for that reaction and  $A : C$  represents a temporary complex, which is necessary for the condensation process to happen.

One of the main features of the model concerns the possibility to create new species by means of the internal dynamics. The creation of new species leads to the creation of new reactions; on the other side, some species could also vanish. To maintain the consistency of the system in the case of reappearance of some of the vanished species, all the reactions are kept in memory.

Another important remark regards the emergence of competition and inhibition phenomena by means of the particle-based algorithmic approach, since the molecules involved in a specific reaction cannot be used in another one at the same time.

Notice that with regard to an asynchronous stochastic model such this, the question on the correct reaction graph to use is of fundamental importance. To this end we introduced three distinct reaction graphs, to be used according to the circumstances. In detail:

- The *possible reactions graph*: in which all the possible reactions at a certain moment of the simulation, including those that will not actually occur, are drawn.

- The *complete reaction graph*: in which all the reactions that occur at least once over the simulation time frame are conserved.
- The *actual reaction graph*: after defining a specific temporal window,  $W$ , only the reactions that occur within  $W$  at a specific time are kept in the graph, while the older ones are removed. Notice that the temporal window turns out to be a key parameter in the analysis of the system, since the detection of ACSs is made using this specific graph representation. In this way it is possible to define cycles even in a stochastic system with asynchronous update and, at the same time, to neglect the influence of very rare reactions on the overall dynamics.

## Introduction of the energy in the model

The first rationale at the base of the introduction of the energy within the model is that energy *does* exist in nature and, to a wide extent, it deeply affects the nature and the dynamics of biophysical and biochemical systems. With regard to our model of catalytic reaction network, both information and matter were present in the original description (Filisetti et al., 2010, 2011a), while energy was missing. Therefore, one of the major objectives of this work is to decipher whether and how energy actually influences the overall dynamical behavior. Moreover, we may hypothesize that the association of energy to some specific type of reaction could lead the system to novel complex behaviors, mostly in regard to the possible emergence of ACSs.

The general idea is to divide the possible reactions in two classes in accordance with the specific energetic constraints, namely *exergonic* and *endergonic* reactions. While exergonic reactions occur releasing energy, endergonic reactions require the presence of energy carrier molecules that release an amount of energy to some of elements involved in the reaction, otherwise the reaction cannot occur<sup>2</sup>.

For simplicity we assume that the exergonic reactions release energy in form of heat (in the present state of the model there is no coupling between exergonic and endergonic reactions) and that the presence of substrates and catalyst is sufficient for them to occur. Constraints on the endergonic reactions are explained below.

It is also important to remark that, in order to maintain a certain degree of generality, no hypotheses on the specific form of energy are formulated. Temperature is assumed to be kept constant by coupling the reactions with a heat bath.

Let us assume the presence of an incoming flux of loaded energy carriers  $\phi_E$  measured in ( $mol/sec$ ), which transport

<sup>2</sup>We could assume the condensations to be endergonic reactions and that, conversely, cleavage reactions occur spontaneously and do not require any chemical energy: these conditions hold, for example, in case of RNA in aqueous environment.

the energy into the system and which instantaneously diffuse in the reactor. The energy carriers, *ECs* from now on, bind and energize the internal species with a energization kinetic constant  $k_{nrg}$ .

Once that an energy carrier has released energy to a specific molecule it is removed from the system (we do not consider the unloaded energy carriers in the dynamics), while that species remains energized until it becomes part of any reactions requiring energy to proceed to completion. We also assume the presence of an outgoing flux of *ECs* coherent with the efflux constant of the reactor  $k_{out}$  and the presence of an *ECs* decay constant  $k_{dec}$ , by which an *EC* can be discarded because of the loss of its energetic load. Such processes are described as in the following:

$$\begin{cases} \frac{d[EC]}{dt} = \phi_E - k_{out}[EC] - k_{dec}[EC] \\ \quad - k_{nrg}[EC][X^-] \\ \frac{d[X^+]}{dt} = k_{nrg}[EC][X^-] - k_{out}[X^+] \\ \quad - k_{dec}[X^+] - \psi \\ \frac{d[X^-]}{dt} = \psi + K + k_{dec}[X^+] - k_{nrg}[EC][X^-] \\ \quad - k_{out}[X^-] \end{cases} \quad (2)$$

where  $[EC]$  stands for the concentration of the *ECs*,  $[X^+]$  represents the overall concentration of the charged molecules,  $[X^-]$  is the total concentration of the uncharged molecules,  $\psi$  represents the decrease of  $[X^+]$ , and the increase of  $[X^-]$ , because of the reactions occurred consuming the energy contained in the species involved in, and  $K$  represents the incoming flux (moles/sec) of uncharged molecules<sup>3</sup>.

It is important to stress that, considering the three-molecular nature of the condensation reactions, and the bi-molecular nature of the cleavage reactions, there are 12 possible combinatorial energy configurations in accordance with the position of the molecules carrying the energetic group: catalyst and/or first substrate and/or second substrate, table 1.

In accordance with table 1, the reactions admitted by the possible different energy frameworks can be thought as two independent Boolean functions, one for the condensation reactions and one for the cleavage reactions, of the respectively 8 and 4 possible input arguments (there are  $2^k$  possible different Boolean functions, where  $k$  is the number of different Boolean inputs).

Nevertheless, only a subset of the overall  $256 + 16$  Boolean functions are biologically plausible according to the adopted assumptions.

<sup>3</sup>Although the model is based on a stochastic algorithm, in order to speed up the computational performance, both the energy flux and the species energization processes are described by means of an approximated algorithm.

	Catalyst	Substrate 1	Substrate 2
Condensation			
1	+	+	+
2	+	+	-
3	+	-	+
4	+	-	-
5	-	+	+
6	-	+	-
7	-	-	+
8	-	-	-
Cleavage			
9	+	+	//
10	+	-	//
11	-	+	//
12	-	-	//

Table 1: In the table all the possible energy configurations are represented. Symbol “+” stands for the charged state of the molecules whereas symbol “-” represents the uncharged state of the molecule.

In principle, if we consider a system composed of a set of distinct interacting chemicals, it would be reasonable to assign distinct energetic Boolean functions to each specific reaction. Of course, there are constraints between cleavage and condensation groups (for a nice and detailed presentation, see (Plasson and Bersini, 2009)); at the present stage of the model we make simple choices compliant with the underlying physical and chemical properties (see below), by leaving more detailed and complex scenarios to future developments.

## Preliminary results

The preliminary analyses regarding the introduction of energy within the model are aimed to understand the influence of a variation of a) the energy carriers incoming flux  $\phi_E$  and of b) the energization kinetic constant  $k_{nrg}$  on the overall dynamics, with particular attention to the emergence of ACSs.

In detail, we considered the specific case in which all the condensations are *endoergonic* reactions and, thus, require energy to occur, and all the cleavages are neutral, since they can occur both in presence and in absence of energy. Furthermore, we decided to concentrate on the case in which a unique Boolean energy function is associated to all the condensation reactions, i.e. the function number 14 (00001110 in binary code), which requires that at least one of the two substrates is energized, while the catalyst of the reaction is necessarily not energized. For the sake of completeness, the Boolean energy function associated to the cleavage is the number 15 (1111 in binary code), that is the *true* function.

We specify that, in the course of this study, we decided

to simulate systems with standard structural parameters<sup>4</sup> and with a *critical* reaction probability, i.e. the probability according to which one random species catalyses, on the average, one random reaction<sup>5</sup>. We made this choice in order to observe whether and to what extent an energy variation in the system affects the emergence of ACSs in the region of the parameters space that is, according to the literature (Farmer and Kauffman, 1986), close to the phase transition.

We analyzed different ensembles of systems in which we varied independently:

- the incoming flux of energy carriers  $\phi_E$ , starting from the benchmark condition in which no carriers are present in the system: 0,  $10^{-23}$  mol/sec (corresponding to 6 carriers/sec),  $10^{-22}$  (60),  $10^{-21}$  (600),  $10^{-20}$  (6000);
- the energization kinetic constant  $k_{nrg}$ :  $10^{-1}$ , 1, 10,  $10^2$ ,  $10^3$ .

In figure 1 we can observe the variation of the average number of species present in the reactor, and not belonging to the incoming flux, at the end of the simulation (i.e. 1000 seconds) as a function of the variation of the incoming flux of energy carriers  $\phi_E$  (x axis) and of  $k_{nrg}$  (z axis).

In those cases in which there are no energy carriers in the system we can see that no new new species are present at the end of the simulation and this is clearly due to the impossibility for the condensations to occur in case of no energy. On the other hand, we can observe a maximum region along

<sup>4</sup>The detailed setting of the system is the following:

- the alphabet is composed of two letters, A and B;
- the firing disk containing the elements present in the reactor at the beginning of the simulation is composed of all the species up to length 4;
- the volume of the reactor is set to  $10^{-18}$  dm<sup>3</sup> and the overall initial concentration is set to  $10^{-4}$ ;
- the influx is composed of all the species of the firing disk and the influx rate is set to  $10^{-21}$  mol/sec;
- monomers and dimers can not be catalysts;
- the number of energy carriers entering the reactor and the value of the energy kinetic constant are varied according to the analyses and they are shown in the captions of the relative figures.

Notice that with these settings around 600 new molecules are entering the reactor every second and that at the theoretical dynamical equilibrium around 30000 molecules would be present inside the reactor.

<sup>5</sup>In this case the reaction probability is set to:  $10^{-4}$

Figure 1: The figure shows the average number of species not belonging to the influx, with concentration greater than 0 from a set of 30 different simulations for each point represented in the graph. On the x axis the variation of  $\phi_E$  is represented while on the z axis the variation of  $k_{nrg}$  is represented.

the direction of the diagonal individuated by the following combination of  $\phi_E$  and  $k_{nrg}$  (respectively): ( $10^{-23}$  - 1;  $10^{-22}$  - 10;  $10^{-21}$  -  $10^2$ ;  $10^{-20}$  -  $10^3$ ), the maximum of the slope being reached in the cases corresponding to the following three combinations of  $\phi_E$  and  $k_{nrg}$  (respectively): ( $10^{-22}$  - 10;  $10^{-21}$  -  $10^2$ ;  $10^{-20}$  -  $10^3$ ), the first one being the absolute maximum.

Even if  $\phi_E$  and  $k_{nrg}$  are independent parameters, their combination actually represents the amount of available energy present in the system: this is the reason why similar values of the variable under analysis (i.e. the number of new species) are observed in relation to different combinations of these parameters. Moreover, the presence of a region of maximum indicates that there is an optimal amount of energy for the system in terms of overall production of new species. For larger values of both  $\phi_E$  and  $k_{nrg}$  the “efficiency” of the system in producing new species begins to decrease. This effect is partially due to the fact that when all the molecules in the reactor are energized the number of not-energized catalysts decrease due to the constraint on the total quantity of energy, as well as the number of possible condensations; hence in accordance with the particular assumptions concerning the chosen energy function, a decrement of the not-energized catalysts slows down the production of new molecules.

In figure 2 we can find the variation of the average concentration produced within the ACSs and within their first-order leaves in correspondence of the above mentioned combinations of  $\phi_E$  and  $k_{nrg}$ .

In figure 3 the variation of the average concentration of

Figure 2: The figure shows the average concentration produced within the ACSs and within their first-order leaves from a set of 30 different simulations for each point represented in the graph. On the  $x$  axis the variation of  $\phi_E$  is represented while on the  $z$  axis the variation of  $k_{nrg}$  is represented.

the species produced by chains of reactions (and not belonging to ACSs) is shown.

We can see that, while the graph regarding the chains closely resembles that of the new species produced by the system, figure 1, confirming an optimal value of available energy in regard to the enhancement of the general activity, for what concerns the molecules produced within the ACSs (and their leaves) a unique point of maximum is reached for the combination  $\phi_E = 10^{-22}$  and  $k_{nrg} = 10^3$ , which also corresponds to the maximum in the creation of new species. Finally, it is important to remark that with most of the combinations of  $\phi$  and  $k_{nrg}$  no ACSs are present in the system at the end of the simulation and this would provide another possible explanation for the difficulty in observing the emergence of ACSs in wet lab experiments: according to these results, a fine tuning of the parameters regarding the energy is needed to allow the system to produce ACSs.

## Conclusions

The introduction of energy constraints associated to specific types of reactions represents a major novelty in the development of our stochastic model of catalytic reaction networks. In this regard, the main aim of this work was to show whether and to what extent the introduction of energy might affect the overall dynamics and, in particular, the emergence of autocatalytic cycles.

To this end, the preliminary analyses on critical systems showed that the combination of two key parameters, namely the incoming flux of energy carriers  $\phi$  and the energization

Figure 3: The figure shows the average concentration produced by chains of reactions from a set of 30 different simulations for each point represented in the graph. On the  $x$  axis the variation of  $\phi_E$  is represented while on the  $z$  axis the variation of  $k_{nrg}$  is represented.

kinetic constant  $k_{nrg}$ , jointly representing the amount of energy available for the endoergonic reactions, is responsible for a remarkable variation of the general activity of the system (indirectly attested by the production of new species). In particular, it was possible to prove the existence of an optimal value of energy, beyond which the activity of the system begins to decrease.

Focusing on the emergence of ACSs, it was then possible to demonstrate that the maximum production of new species is observed in the case of systems with optimal values of energy, which contain ACSs involving a large number of molecules, hence confirming their relevance in the overall dynamics. On the other hand, with most of the tested combinations of  $\phi$  and  $k_{nrg}$  ACSs could not be detected and this might provide another possible explanation to the difficulty in observing their emergence in wet lab experiments. Moreover, as we already showed in (Filisetti et al., 2011a, 2010), the autocatalytic sets are not robust and in most of them the catalytic closure is achieved by means of a “bottleneck” reaction occurring rarely during the simulations; although the energy constraints allow the emergence of structural ACSs, they do not confer neither robustness nor some forms of self-sustaining dynamics.

The results show that our model might unravel some unexpected features concerning the emergence of autocatalytic sets of molecules as for example the presence of an optimum in the energy flux.

Thus, several developments are underway in order to refine the description of the model like, for instance, the associa-

tion of distinct energization Boolean functions and of distinct  $k_{nrg}$  to different reactions and species, with the purpose of investigating possible complex behaviors related to the availability of energy.

## Abstract

Pleiotropy and epistasis are central to understanding how genes are expressed. Kauffman's NK model is used ubiquitously to investigate gene expression in evolution and other contexts; it is widely understood to reflect the results of epistasis, but it is less often used to study pleiotropy. In this paper we introduce the NEP model, a variant of the NK model which allows epistasis and pleiotropy to be studied individually. We apply our methods to global and local optima and adaptive walks, and elucidate new insights into Kauffman's complexity catastrophe.

## Introduction

Pleiotropy, which refers to a single locus affecting more than one trait, and epistasis, several loci collectively affecting a single trait, have long been recognized to be fundamental to our understanding of gene expression (Tyler et al., 2009). Epistasis is widely encountered in humans (Moore, 2003) and other organisms (Remold and Lenski, 2004; Bonhoeffer et al., 2004), as is pleiotropy (Ostrowski et al., 2005; Wagner et al., 2008; Scarcelli et al., 2007). Epistasis and pleiotropy are also seen to play a key role in evolution (Phillips, 2008; Fenster et al., 1997). Thus it is important to form a clear picture of the mechanisms of epistasis and pleiotropy and their effects on phenotypes.

Kauffman's NK model (Kauffman and Levin, 1987), a computational model of genomes in fitness landscapes, has been widely used to investigate properties of fitness spaces (Kauffman, 1993; Weinberger and Stadler, 1993; Macken and Perelson, 1989; Orr, 2005) and evolution thereon (Østman et al., 2010). A number of variants of the NK model have also been studied, such as the infinite-allele variant (Welch and Waxman, 2005) and the block model (Perelson and Macken, 1995); the NK model and its variants have been shown to be applicable to a variety of biological phenomena (Macken and Perelson, 1989; Perelson and Macken, 1995; Kauffman and Weinberger, 1989; Orr, 2006).

Epistasis and pleiotropy can be tuned in the NK model, but they always vary in tandem, which makes it difficult to study the two effects separately. In this paper we describe

the NEP model, a variant of the NK model in which epistasis and pleiotropy can be tuned independently.

## Methods

### Models

**The NK Model** The NK model comprises a population of genomes, each of which consists of  $N$  loci, with  $A$  alleles at each locus. The model defines one trait for each locus; the locus interacts epistatically with  $K$  other loci in determining that trait. The fitness of a genome is calculated by averaging the fitness contributions of all of the traits. Each trait is represented by a  $(K + 1)$ -dimensional table, with the length along each dimension equal to  $A$ , where the values in the table are stochastically chosen from a uniform distribution. The fitness contribution for each trait is selected from the table by choosing the row corresponding to the allele of the base locus, the column corresponding to the allele of the next locus, etc.

Choosing which other loci interact with a given locus can either be done deterministically, by having each locus interact with the succeeding  $K$  loci (where the genome is assumed to be circular), or stochastically, by choosing  $K$  other loci at random. Because the NK model contains a trait/table for each of the  $N$  loci, there are  $N$  traits/tables in total. In the rest of the paper we will refer to traits and tables interchangeably.

Fig. 1 gives an example genome with its associated tables; the top part of this figure refers to the NK model, and the bottom part contains tables that are added for the NEP model. In this example  $N = 4$  and  $A = 2$ , so each genome contains 4 loci with 2 alleles each; the interaction degree,  $K$ , is 1. The horizontal bar in the middle of the diagram is the genome, and the 4 dots on the bar are the loci. The numbers 0, 1, 1, 0 along the genome are the alleles at each locus.

In this example, each consecutive pair of loci interact in a trait, as do the outer two loci, for a total of four traits. Each trait is shown in the diagram as a two-dimensional lookup table above the genome, which is linked to its pair of loci by a pair of lines. The first pair of alleles is (0, 1), so the corresponding fitness contribution is the .71 shown in the

Figure 1: An example genome with its tables. The genome, with alleles, runs across the center of the figure; each pair of loci is linked to a table which represents the trait determined by that pair of loci. The single entry shown in each table is the fitness chosen by the allele values of the corresponding loci. The four tables along the top of the figure constitute an NK model, and all six tables together form an NEP model.

0th row and the 1st column; the fitness contributions for the other pairs of loci are shown similarly. (In an actual instance of the model, of course, all of the values in each table would be filled in.) The overall fitness of the genome is then the average of the four lookup values.

The parameter  $K$  has traditionally been used to tune the degree of epistasis in the model:  $K$  determines the degree of epistasis, because each locus in the model interacts with  $K$  other loci. However, we note that  $K$  also determines the degree of pleiotropy, because each locus appears in  $K + 1$  tables. The NK model has no way to separate epistasis from pleiotropy, however, which can lead to uncertainty about which of the two is causing any particular observed effect.

**The NEP Model** In order to separate epistasis from pleiotropy, we introduce the NEP model, adding the two new parameters  $E$  and  $P$ . To assist in describing  $E$  and  $P$ , we define  $T$  as the number of tables in the model. For  $i$  from 1 to  $T$ ,  $E_i$  is the number of loci in the  $i$ th table — in other words, the number of loci that are used to look up the value in the  $i$ th table. The loci used in each table are chosen at random. We refer to  $E_i$  as the epistatic dimension of table  $i$ . For  $j$  from 1 to  $N$ ,  $P_j$  is the number of tables in which the  $j$ th locus appears, referred to as the pleiotropic dimension of that locus. The NEP model is a generalization of the NK model, and the parameters  $E$  and  $P$  can be seen in the NK model: since the parameter  $K$  refers to how many *other* loci a given locus interacts with, while our parameter  $E$  refers to the *total* number of interacting loci, any given NK model has  $K = E - 1$ ; similarly,  $K = P - 1$ . The difference between the NK model and the NEP model is that the NK model fixes  $P \equiv E$  but the NEP model allows  $P$  to be different from  $E$ .

When two or more loci interact epistatically in the NEP

model, the fitness contribution for that interaction is chosen from a stochastic lookup table. The stochasticity of the lookup table means that the interaction between the loci in determining the fitness is highly non-linear, consistent with the usual definition of epistasis.

Since a genome can have  $A$  possible values at each locus, there are a total of  $A^N$  genomes in the fitness space in either the NK model or the NEP model.

In the example of the NK model in Fig. 1 described above,  $E = 2$  and  $P = 2$ ; as always in the NK model,  $P \equiv E$ . However, in the NEP model we can modify the example to have  $P$  differ from  $E$ , by adding the two tables shown below the genome. The dimension  $E$  of each table is still 2, but now each locus is linked to 3 tables, so  $P = 3$ .

Referring to Fig. 1, there are two ways to count the links between the genome and the trait tables: If we count the links where they connect to the tables, we get  $\sum_{i=1}^T E_i$  since the epistatic dimension of each table is equal to the number of links connecting to it. On the other hand, if we count the links where they connect to the loci on the genome, we get  $\sum_{j=1}^N P_j$  since the pleiotropic dimension of each locus is equal to the number of links connecting to it. Since those two counts must be equal, we find that

$$\sum_{j=1}^N P_j = \sum_{i=1}^T E_i. \quad (1)$$

This equation can be rewritten as  $N\bar{P} = \bar{E}T$ , where  $\bar{P}$  and  $\bar{E}$  are the average values of  $P_j$  and  $E_i$  respectively. In practice we usually either choose to have  $P_j \equiv P$ , or choose to have  $E_i \equiv E$ . In this paper we take the former approach.

Note that the embedded-landscape model (Altenberg,

1994; Heckendorn et al., 1999) has previously introduced flexibility in the number of tables to the NK model, in the same way as the NEP model; however, the embedded-landscape model has generally been used in studies of computational complexity and has typically not delineated the effects of epistasis and pleiotropy.

## Numerical Analysis

The current study employs an NEP model with  $N = 20$  and  $A = 2$ . We simulated 400 different models: for  $P$  equal to each of 1 through 20 we chose, using the equation  $NP = \bar{E}T$ , the value of  $\bar{E}$  closest to each of 1 through 20, for a total of 400  $(P, \bar{E})$  pairs. When  $\bar{E}$  was an integer we chose all of the tables to have that value for  $E_i$ . When  $\bar{E}$  was not an integer we chose some of the tables to have  $E_i$  equal to the next integer below  $\bar{E}$ , and some the next integer above, with the counts of each chosen to give the desired average  $\bar{E}$ . This ensured that the tables were as similar in size as possible. Each pair  $(P, \bar{E})$  gave a model, and each model was run 100 times, populating the lookup tables with a different random seed each time; all of the statistics for each model were averaged across those runs.

Among the phenomena we study here are local optima and adaptive walks, both of which are important in studying the dynamics of evolution (Orr, 2005). If the fitness of a given genome is greater than the fitness of any genome at a Hamming distance of 1 from the given genome, that fitness is said to be a local optimum. An adaptive walk is a sequence of genomes that starts at a randomly-selected genome and proceeds by single fitness-improving mutations until it reaches a local optimum.

We collected the following statistics: variance in fitness within each fitness space; global optimum fitness, defined as the largest fitness value in the fitness space; mean local optimum fitness; number of local optima in the fitness space; average length of adaptive walks, defined as the number of fitness-improving mutations traversed in the walk; fitnesses attained in adaptive walks, defined as the fitness of the last genome in the adaptive walk (by definition, a local optimum); first step up in adaptive walks, defined as the difference in fitness between the first genome and the second genome in an adaptive walk; last step up in adaptive walks, defined as the difference in fitness between the second-to-last genome and the last genome in an adaptive walk; and the maximum step up, defined as the largest difference in fitness between any two adjacent genomes in the fitness space. These are some of the most commonly-measured statistics in studies of the NK model (Kauffman, 1993; Macken and Perelson, 1989) and its variants (Perelson and Macken, 1995).

In each run, the variance, the global optimum, the mean local optimum, and the number of local optima were calculated by iterating across all  $2^{20}$  genomes in the fitness space. The maximum step up was calculated by iterating

across all pairs of genomes. To calculate statistics on adaptive walks, 1,000 adaptive walks were simulated in each run; each reported statistic is then the average value of that statistic across the 1,000 adaptive walks simulated.

Representative results from the 400 models are described below.

## Results

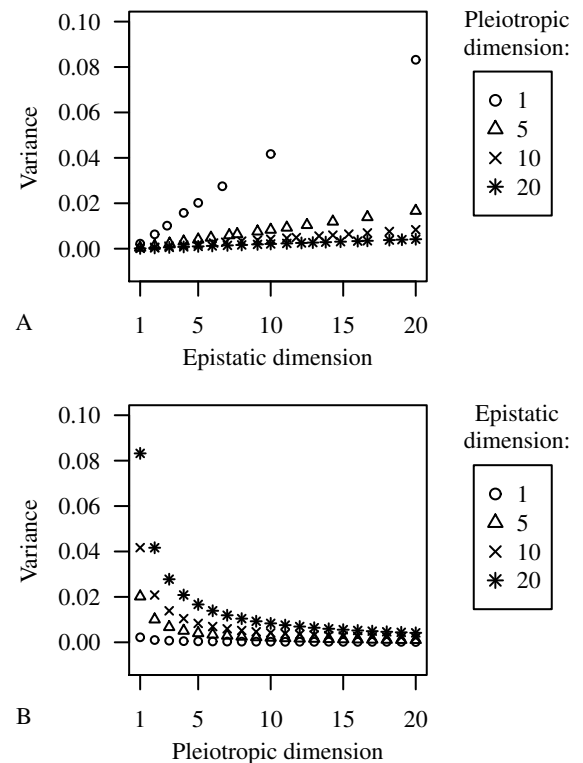

Figure 2: Fitness variance by epistatic dimension and pleiotropic dimension.

## Fitnesses and Optima

Variance in fitness increased approximately linearly with epistatic dimension (Fig. 2A) and decreased with pleiotropic dimension (Fig. 2B). This can be understood by considering what happens when we increment either the epistatic dimension or the pleiotropic dimension. First, if we increase  $\bar{P}$  by 1 while holding  $\bar{E}$  fixed, the equation  $N\bar{P} = \bar{E}T$  tells us that we need to multiply  $T$  by  $(\bar{P} + 1)/\bar{P}$ . Since the fitness of any given genome is calculated by averaging one entry from each of the  $T$  tables, multiplying  $T$  by  $(\bar{P} + 1)/\bar{P}$  means that each calculated fitness is averaged across more table-entries, which decreases the fitness variance.

Secondly, consider incrementing  $\bar{E}$  while holding  $\bar{P}$  fixed. This requires us to multiply  $T$  by  $\bar{E}/(\bar{E} + 1)$ , decreasing the value of  $T$ , which has the opposite effect to

incrementing  $\bar{P}$ : it increases the variance of fitnesses. Incrementing  $\bar{E}$  also increases the variance by increasing the degrees of freedom of the model, which is equal to the number of separately-generated stochastic table-entries. Since each table contains  $A^{\bar{E}}$  entries, for any given values of  $A$ ,  $\bar{E}$ , and  $T$ , the number of separately-generated stochastic table-entries is

$$TA^{\bar{E}}. \quad (2)$$

If we increment  $\bar{E}$  while holding  $\bar{P}$  fixed then the new total number of entries is given by

$$T \frac{\bar{E}}{\bar{E} + 1} A^{\bar{E}+1}. \quad (3)$$

Thus the net effect of incrementing  $\bar{E}$  is to multiply the number of separately-generated stochastic table-entries, and thus the degrees of freedom, by  $A\bar{E}/(\bar{E} + 1)$ . For  $A = 2$ , this is greater than 1 as long as  $E > 1$ .

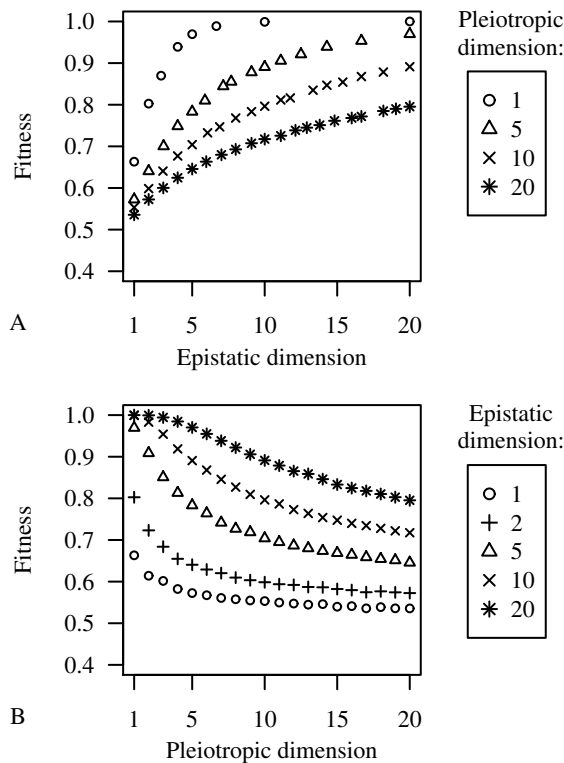

Figure 3: Global optimum fitness by epistatic dimension and pleiotropic dimension.

Fitnesses of global optima increased with epistatic dimension; for smaller pleiotropic dimension (up through about 5) the global optimum approached 1.0 (Fig. 3A). The global optima decreased with pleiotropic dimension (Fig. 3B). The global optimum is an extreme value of fitness, so as the variance increases with epistatic dimension, the global optimum

also increases. The opposite argument shows why the global optimum decreases with pleiotropic dimension.

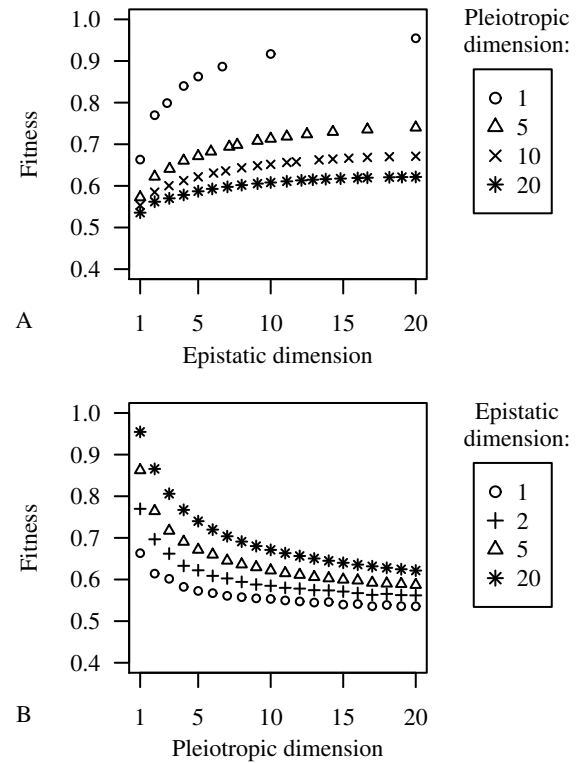

Figure 4: Local optimum fitness by epistatic dimension and pleiotropic dimension.

As with global optima, fitnesses of local optima increased with epistatic dimension (Fig. 4A) and decreased with pleiotropic dimension (Fig. 4B). Since local optima are local extreme values, the same argument as with global optima indicates why local optima increase with epistatic dimension and decrease with pleiotropic dimension.

The number of local optima increased dramatically with epistatic dimension (Fig. 5A); for high and low epistatic dimensions, the number of local optima did not vary with pleiotropic dimension, but for intermediate epistatic dimensions, lower pleiotropic dimensions gave slightly higher numbers of local optima (Fig. 5B). Note also that for an epistatic dimension of 2, the graph of the number of local optima by pleiotropic dimension is a little noisy; later we will notice the same phenomenon in a different way with the lengths of adaptive walks.

Kauffman proves (Kauffman, 1993) that for  $K = N - 1$  the number of local optima is very large; the proof uses only the epistasis effects of  $K$ , not the pleiotropy effects. The results we get here are consistent with that, in that the number of local optima increases with epistatic dimension but varies little with pleiotropic dimension.

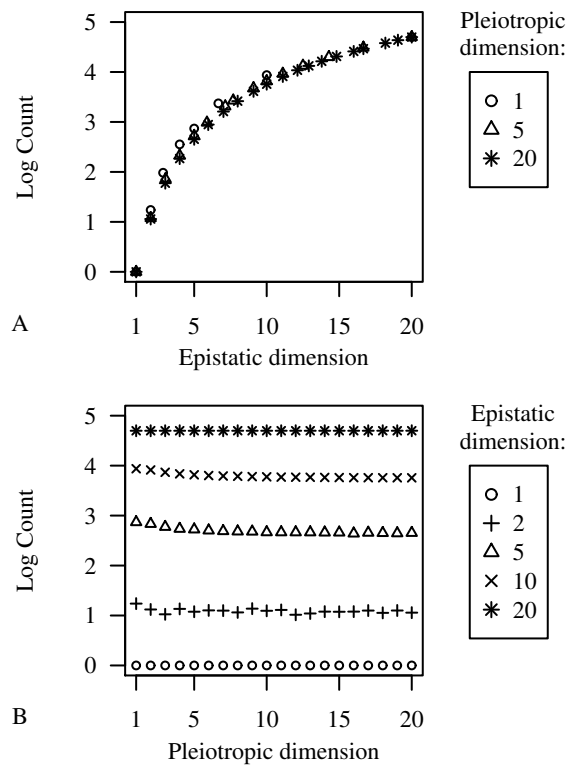

Figure 5: Log number of local optima by epistatic dimension and pleiotropic dimension.

## Adaptive Walks

In general the length of adaptive walks decreased with epistatic dimension (Fig. 6A) and increased or held steady with pleiotropic dimension (Fig. 6B). For epistatic dimension of 1 the average length was 10, regardless of pleiotropic dimension; otherwise, for each pleiotropic dimension, the average length peaked at an epistatic dimension of 2 and decreased from there. For epistatic dimension between 2 and about 10, lengths of adaptive walks increased as a function of pleiotropic dimension.

Kauffman proves (Kauffman, 1993) that in an NK model where  $A = 2$  and  $K = 0$  the average length of an adaptive walk is  $N/2$ . Again, the proof uses only the epistasis effects of  $K$ , and thus holds for the NEP model; this explains why the average length is 10 in our models when the epistatic dimension is 1 (which is equivalent to  $K = 0$ ). For epistatic dimensions greater than 1, the average adaptive-walk length is inversely related to the number of local optima, and thus it decreases with epistatic dimension and increases with pleiotropic dimension for low epistatic dimensions. The inverse relationship with number of local optima is also why we see the same noisiness in the graph of adaptive-walk length by pleiotropic dimension for epistatic dimension of 2 as we did with the number of local optima.

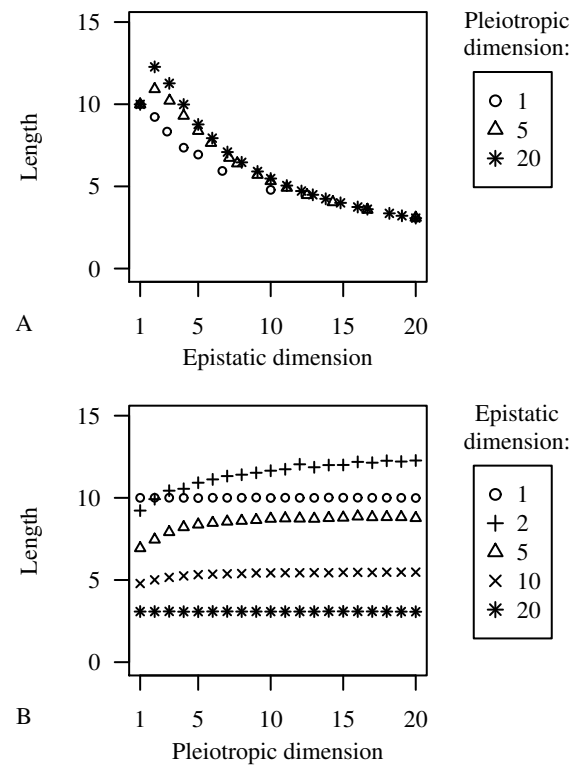

Figure 6: Length of adaptive walks by epistatic dimension and pleiotropic dimension.

Attained fitness in adaptive walks increased with epistatic dimension, with the effect being most pronounced for low pleiotropic dimension (Fig. 7A); attained fitness decreased with pleiotropic dimension (Fig. 7B).

Adaptive-walk lengths decrease with epistatic dimension but attained fitnesses increase; the opposite is true with respect to pleiotropic dimension. This apparent contradiction is resolved by Figures 8 and 9, which show the typical steps in adaptive walks.

The typical first step up in an adaptive walk increased with epistatic dimension (Fig. 8A) and decreased with pleiotropic dimension (Fig. 8B). The same is true for the typical last step (Fig. 9), with one exception: for epistatic dimensions greater than about 10, the typical last step up was lower for a pleiotropic dimension of 1 than for the next few pleiotropic dimensions. Again we see the effects of variance: increasing the variance with epistatic dimension allows for larger steps up, while decreasing it with pleiotropic dimension decreases the possible steps up. The phenomenon whereby average steps up increase with increasing  $K$  in the NK model, allowing higher fitness to be achieved with fewer steps, has been observed by Østman et al. (2010), who ascribed the phenomenon to a combination of pleiotropy and epistasis. In contrast, we find that the increasing amplitude of steps up is due solely to increasing epistasis, not increasing pleiotropy,

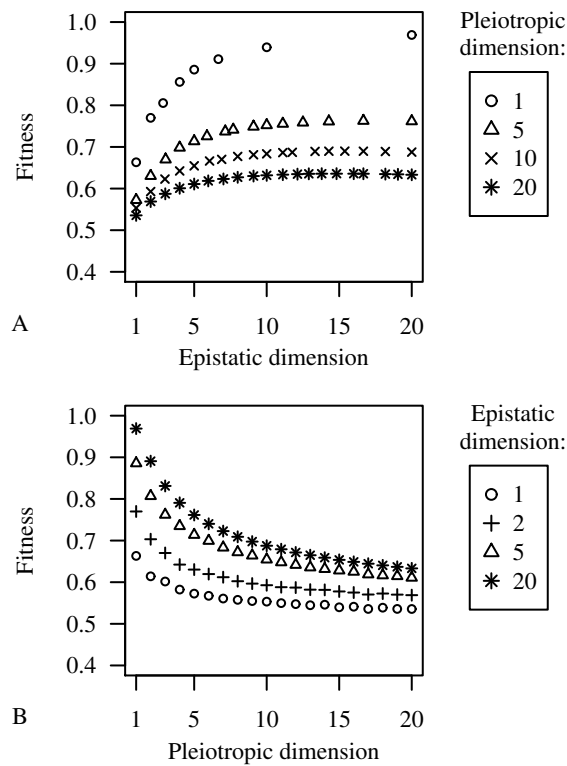

Figure 7: Attained fitness of adaptive walks by epistatic dimension and pleiotropic dimension.

and, in fact, that amplitudes of steps up decrease with increasing pleiotropy.

Except for an epistatic dimension of 1 (where they were the same), the typical last step was less than the typical first step for all epistatic dimensions and pleiotropic dimensions; the effect was more pronounced for higher epistatic dimension and lower pleiotropic dimension. The reason for this is that on the last step of an adaptive walk the fitness of the genome is already quite high, limiting the remaining steps available.

The maximum step up, defined as the largest difference in fitness between two adjacent genomes, increased with epistatic dimension (Fig. 10A) and decreased with pleiotropic dimension (Fig. 10B). Again we see the result of the fact that fitness variance increases with epistatic dimension and decreases with pleiotropic dimension.

## Discussion

In the NEP model, referring to the equation  $N\bar{P} = \bar{E}T$  we see that one way to increase the pleiotropic dimension  $P$  is by increasing  $T$  by adding one or more traits. As the results here have shown, increasing pleiotropy in this way tends to decrease the local and global optima. On the other hand, when a biological species adds a trait its fitness generally goes up; it may be that when a biological species adds a trait

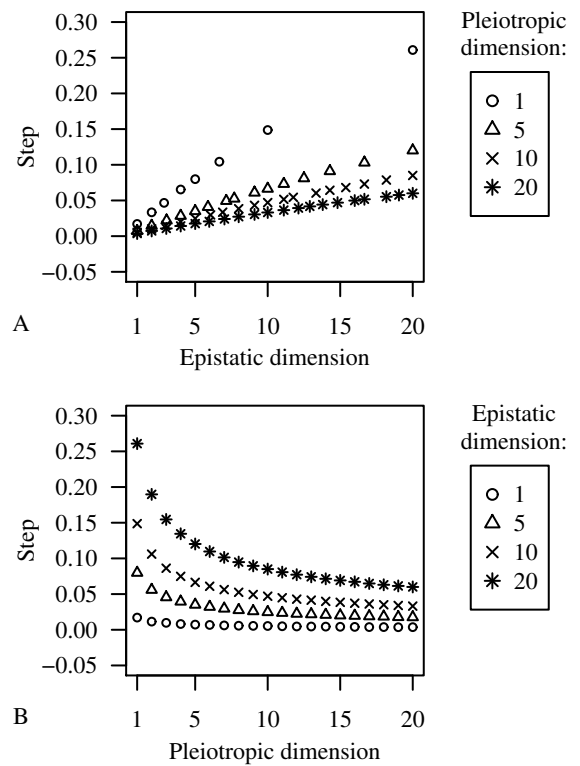

Figure 8: First step of adaptive walks by epistatic dimension and pleiotropic dimension.

it also increases the overall number of loci, thus avoiding an increase in pleiotropy. Further investigation will be required to resolve this question.

## Effects of Epistasis and Pleiotropy

The overall effect of epistasis is to increase the variance in fitness, and of pleiotropy to decrease it. We see this first in the direct measurements of variance of fitness; we also see it in measurements of global and local optima: less variance reduces the heights of the available maxima. Attained fitnesses in adaptive walks match closely with mean local optima, so they, too, decrease with decreasing variance. First and last steps in adaptive walks, and maximum single steps, also trend in the same direction as variance. The situation here is more complicated, however: because a single step means mutating a single allele, we are very far from the extreme-value considerations that apply to global and local optima.

A key difference between the NEP model and the embedded-landscape model is that the latter does not fully separate the effects of epistasis and pleiotropy. For example, (Smith and Smith, 1999) find that “the epistasis parameter  $K$  has little effect on the global fitness statistics, and does not affect the mean fitness values of the local optima at all.” However, when we separated epistasis out from pleiotropy,

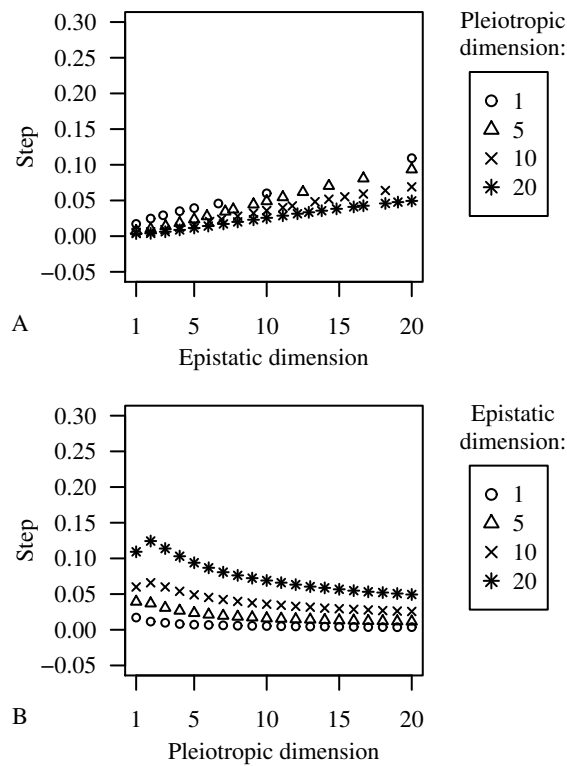

Figure 9: Last step of adaptive walks by epistatic dimension and pleiotropic dimension.

we found a clear dependency of global optimum fitness and mean local optimum fitness on epistasis.

### The Complexity Catastrophe

In working with the NK model, Kauffman observed a tendency for fitnesses of local optima to decrease with increasing  $K$ , and coined the term “complexity catastrophe” to describe this (Kauffman, 1993). Previous authors have ascribed the decrease in local optima to an increase in epistasis (e.g., Kauffman (1993); Solow et al. (1999)); in contrast, in the context of the embedded-landscape model (Smith and Smith, 1999) stated that the decrease in local optima is due to an increase in the number of traits.

The results described here allow us to clarify which part of the complexity causes the catastrophe. As pleiotropic dimension increases, both attained fitnesses and the fitnesses of local optima decrease. On the other hand, as epistatic dimension increases, both attained fitnesses and the fitnesses of local optima *increase*. The culprit in the complexity catastrophe is simply that decreasing variance lowers the local optima.

Kauffman further observed that as  $K$  increases, the mean value of local optima initially increases, and then starts to decrease. Looking at parts A and B of Fig. 4, we see the explanation of the observed trends: Increasing  $K$  corresponds

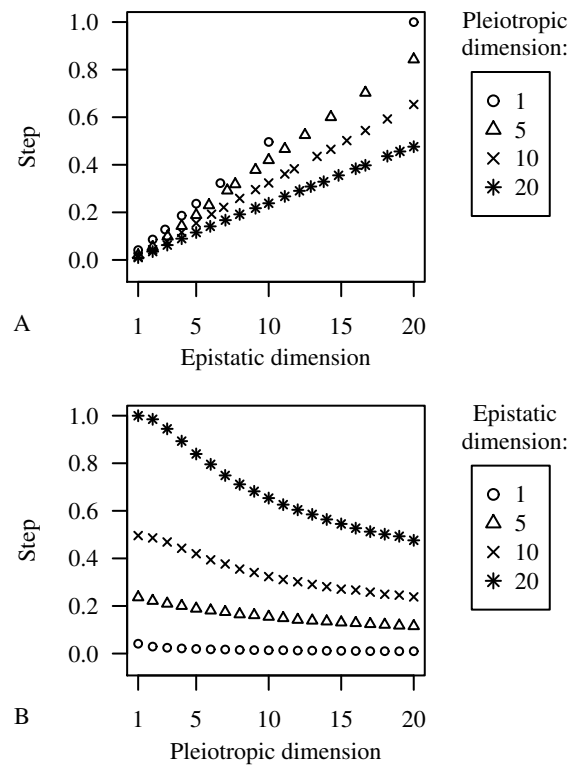

Figure 10: Maximum single step by epistatic dimension and pleiotropic dimension.

to increasing  $E$  and  $P$  simultaneously, which results in simultaneous tendencies to increase and decrease local optima, respectively; at first the former tendency predominates, and then the latter.

### Conclusion

Given the ubiquity of epistasis and pleiotropy in gene expression, and given the prevalence of the NK model in studying genetic phenomena, it is important to ensure that we fully understand those two forms of gene linkage in the context of the NK model. As described here, the NEP model can be used to distinguish the effects of epistasis and pleiotropy, allowing assumptions made in the literature to be re-examined, and allowing new insights to be gained going forward.

## Abstract

The insights gained from the study of complex systems in biological, social, and engineered systems enable us not only to observe and understand, but also to actively design systems which will be capable of successfully coping with complex and dynamically changing situations. The methods and mindset required for this approach have been applied to educational systems with their diverse levels of scale and complexity. Based on the general case made by Yaneer Bar-Yam, this paper applies the complex systems approach to the educational system in Switzerland. It confirms that the complex systems approach is valid. Indeed, many recommendations made for the general case have already been implemented in the Swiss education system. To address existing problems and difficulties, further steps are recommended. This paper contributes to the further establishment complex systems approach by shedding light on an area which concerns us all, which is a frequent topic of discussion and dispute among politicians and the public, where billions of dollars have been spent without achieving the desired results, and where it is difficult to directly derive consequences from actions taken. The analysis of the education system's different levels, their complexity and scale will clarify how such a dynamic system should be approached, and how it can be guided towards the desired performance.

## Introduction

The principles of complex systems have been successfully applied to a diversity of problems Bar-Yam (2004), including the health system, military warfare, international development and educational systems. Although still in its initial phase, the effects obtained through using a complex systems approach – also called “Enlightened Evolutionary Engineering” – are generally promising. At the moment, further validation to increase the credibility of this approach is still required. This paper thus applies the complex systems approach to the educational system in Switzerland. As it turns out, the Swiss system – which functions rather well in comparison with other education systems – already uses several of the recommended principles. Examples include offering a variety of ways towards professional qualifications, and using a diversity of actions to provide for the individual students' needs. To address remaining or new problems, the

complex systems approach should be applied consequently, as detailed in this article.

Complex systems can help us improve our educational systems by making us understand the differences between diverse levels within the educational system and the respective approaches they require. We will understand why certain educational systems perform better than others by discussing the “one fits all” uniform large-scale approach as compared to diversity and individuality.

The motivation for applying complex systems thinking to educational systems is that our societies are becoming increasingly complex and intertwined. The modern globalised world needs mainly specialists – people who are particularly good at a few things, which often do not correspond to classical school teachings; some “all-rounders”, who are good at many things, will make connections between them. When educating today's and tomorrow's generations – enabling them to be valuable citizens that contribute to a successful society<sup>1</sup> – the educational system must provide people with a certain minimal common background. Moreover, and potentially even more important, the educational system must help specialists acquire their particular skills and knowledge which will make them the valuable resources of society.

Building and maintaining a well-performing educational system, which is able to cope with varying conditions and stresses given through migration, economical crises, changing professional requirements and other factors, is a very challenging task. Growing difficulties in the educational systems manifest themselves all over the world, and it is time to find innovative solutions.

The author of this paper has thorough knowledge of the Swiss educational system, not only through her own experience, but also because over the last 6 years she has been closely involved with primary schools and in touch with universities of teacher education in Switzerland, through the

<sup>1</sup>Although, according to Davis and Sumara (2006), there is considerable philosophical controversy about the purpose / effect of education. For the scope of this paper, we will assume that the purpose of education is to enable people to become valuable citizens that contribute to a successful society which includes the dignity and welfare of as many citizens as possible.

KIDSinfo project, <http://www.kidsinfo.ch>. It was launched by the Swiss Association of Women Engineers, SVIN, to pique school children's and particularly girls' interest in technology.

*Organisation of this article:* The second section details the typical problems of many educational systems. The third section explains relevant system characteristics. The fourth section looks at scale and complexity found at different levels in the educational system. The fifth section brings up several controversial issues. The sixth section introduces the case study made on the educational system in Switzerland. The seventh section presents related work. Finally, the eighth section draws conclusions and makes further recommendations.

### Problems in educational systems

It is a widely supported observation that in almost all countries – to a varying degree – young people increasingly have problems finding their ways in society. Another indicator of trouble is that in standardised tests applied across one or several countries, such as the PISA tests (the Organisation for Economic Co-operation and Development (OECD) Programme for International Student Assessment), performance is often poor. Well-regarded schools or countries frequently fail to meet the expectations.

Generally speaking, many educational systems are high in cost but low in efficiency, and lots of social problems surface with or without observable trigger. Many schools complain about disruptive behaviour, violence, cheating, students dropping out, etc.

Reforms of the traditional type have shown close to no improvement; multi-billion \$ projects such as “No child left behind” in the USA were abandoned after years of efforts in vain because the large scale actions taken failed to bring the desired effects.

The point is that people have diverse backgrounds, skills and preferences; therefore, a “one fits all” approach does not work well in many cases because it fails to take people's individuality and their different ways of interacting and learning into account. While the “average” students may react well to an “average-fitted” approach, there will always be plenty of students that will not – for instance, because they are overstrained, under-challenged, because their interests are not met, or because they do not understand the importance of education for their life.

In this situation, insights gained from complexity science may help. Such an approach takes into account the importance of scale and complexity at various levels in the educational system, and may help provide the system with suitable tools at the right level.

Learning is itself a highly complex process which involves many different factors and perspectives, such as individual sense-making, teacher-student relationships, class-

room dynamics, school organisations, community involvement, bodies of knowledge, and culture (Davis and Sumara, 2006); knowing, knowing how to do, and knowing how to be (Lelouche and Morin, 1997). Bar-Yam (2004) discusses both the inherent complexity of learning itself as well as the different levels of complexity in educational systems; concrete examples generally refer to education in the USA. Other authors are cited in the related works section of this paper; our main focus here is on the system which provides the students with opportunities for learning while motivating their curiosity and creativity.

### System characteristics

The original Latin word *complexus* signifies *entwined* or *twisted together* (Heylighen, 1996). A complex system is thus made of more than one part, and the parts are at the same time distinct and connected. It is therefore inherently difficult to model them. Often, there are circular causal relationships: one part influences the other, which in turn influences the first, and so on. This description definitely fits educational systems, with their multi-lateral interactions between teachers, students, their parents, families and friends, teachers' and students' associations, politicians, economy, and the society in general.

Due to its distributed nature, the educational system has weak interdependences between individual classrooms and between individual schools. What happens at one local school does not automatically have much to do with what happens at other schools, in other neighbourhoods or other cities. Schools are strongly influenced by local conditions, and within a certain school, what happens inside a certain classroom is strongly dependent on the teacher, the course to be taught, the students, and their parents. This leads to random quality (influenced by many local and some global factors).

Many system behaviours are local and fine scale – at the level of the individual student or teacher and the interactions they engage in with others. The difficulties encountered are often very particular to a certain case; an action successfully taken in one case may fail in another similar case.

Generally speaking, systems with high variety perform well when faced with complex challenges. This means that a system which is itself complex enough and has a variety of ways to address individual problems will be successful when facing a situation of high complexity and variety, as taught by the *Law of Requisite Variety* (Ashby, 1956). This certainly also applies to educational systems and the challenges they must cope with.

Many different ways of learning exist, including visual, auditive, tactile and other stimuli, and “learning by doing”. Learning in diverse ways provides people with diverse ways of addressing challenges, which in turn often triggers innovation and thus economic growth. This means that it should be in the educational system's very best interest to provide

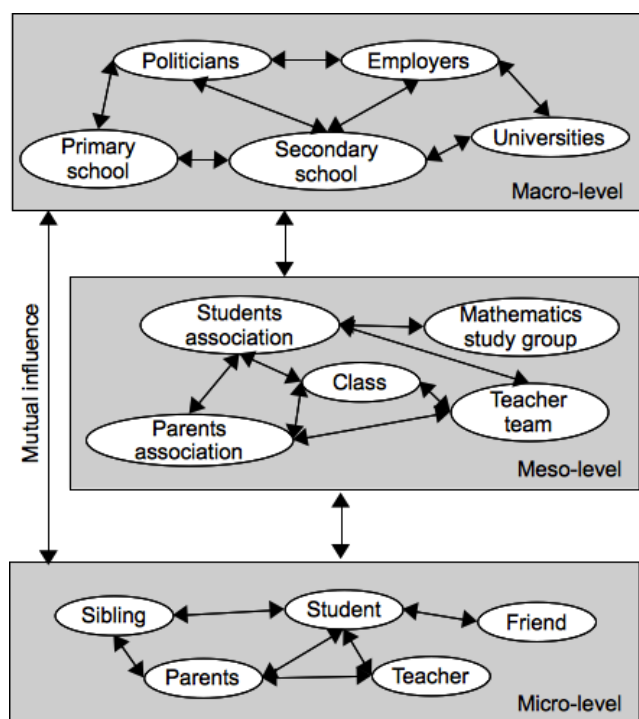

Figure 1: Examples of entities and their interactions at different levels of the educational system (non-exhaustive)

a variety of ways for people to learn. The goal should be to achieve a great variety of skills with consistently high quality, in whatever area of expertise.

The guideline should be to think globally – in terms of the entire educational system and the goals to reach for the benefit of the society – but to act locally – at the level of the individual students, teachers, or groups of them, and taking into account their individual conditions, problems, goals and influencing factors.

### Complexity at different levels

As already mentioned, educational systems typically have several levels of diverse complexity and scale. We discern three of them (although more differences might be made in-between). Figure 1 illustrates this with some examples; other levels and other entities and relations between them exist but have been omitted for the sake of readability.

- **Micro-level / local level:** Education is highly complex at the level of the individual student, his / her capabilities and interests. Many different interrelations are important, including those between student and teacher, student and parents / family / close social environment / other students, and parents and teacher. Actions to take effect at this level must be small-scale and individual. Higher level uniformity of the local tools and actions is not indicated; what works in one case may fail in another.

- **Meso-level / intermediate level:** The complexity at the level of groups of students with similar interests and capabilities is medium, and effective actions can be of medium scale, as they will address student associations, study groups, parents associations or teacher teams. A certain coordination at the meso-level makes sense, as is actions at this level concern groups of people.

- **Macro-level / global level:** Large scale uniform approach can be used at a higher level, including the definition of minimal educational standards for the society to function, teacher education which provides a set of skills for individual action, and teacher support, giving them tools and organisations as required to fulfill their tasks. A lack of coordination or uniformity at the macro-level puts a system in danger of becoming disorganised and confusing.

Taking these differences in scale and complexity into account assures an effective approach to the existing difficulties at each level, because the actions taken are suitable in scale, scope and complexity.

### Issues to be addressed

This section discusses several aspects of importance for a successful education system.

**The right moment for specialisation:** Certain aspects of the educational system are known to be very controversial; among others, the right age for specialisation. It is known from cognitive research that key connections and processes in the brain are established at an early age. This would speak in favour of an early specialisation, so that children would develop their special skills under optimal conditions. On the other hand, children may need enough time to learn a broad variety of skills and develop large general knowledge before even being able to decide which their favourite area shall be. A scientifically sound and generally accepted answer to this topic has not been found yet.

**People's critical attitude towards teachers:** It is an interesting observation that we are highly critical of teachers, but very little critical of medical doctors, although the latter ones have just as much responsibility for our well-being as the former ones, and both of them are human and thus prone to errors. While teachers carry a good part of the responsibility for our positive development on the mid- and longer term, doctors' interventions are often on the shorter term (we typically ask for their help when something is wrong; only few of us consult doctors for advice while everything is fine).

One possible reason for these different perceptions of responsibility and well-being may be that (in most countries) we have a certain freedom to choose who to take as our doctor; if we are not happy with one, we can move on to the

next, until we are satisfied. There is thus a certain competition between doctors of the same specialty. Teachers, however, do not compete with each other, and people have mostly no possibility to choose which one we want to trust with our / our children's education. In some countries, people can choose to which school they want to send their children, but there, the selection possibilities end, and they must accept the teachers they are given. On the other hand, private and higher level schools get to select their students by specifying minimal performance requirements or through other selection procedures.

A way of changing this situation would be to introduce mechanisms for competition and mutual selection of students and teachers in the educational system. The following versions are imaginable:

- Let schools choose students. Let students choose schools. Both versions already exist for private schools and higher / specialised education institutions.
- Let students choose teachers. Let teachers choose students. Neither version does usually exist, to the best of the author's knowledge. If two or more teachers offered exactly the same course, the students' way of choosing a teacher would depend on his / her teaching style and personality. Some teachers might be much more popular than others, and their classes would very quickly be fully booked. They may then either accept students on a "first registered, first served" basis, or select students based on their performances and characteristics. This would naturally lead to inequalities and tension, which may be morally controversial. Competition for scarce resources is, however, also an important principle of how biology and healthy economies function. It would be very interesting to study the effect of such a mechanism on education.

The problem with introducing competition between teachers is that it would add an additional and potentially deceptive performance criterion. Popular teachers are not automatically those which succeed best in transmitting the required knowledge and skills; the most popular teachers may simply be the best entertainers or those which challenge their students less than their fellow teachers. An analogue phenomenon was observed by Ficici and Pollack (1998) when studying the similarities between co-evolution and some educational systems. In their case, each "team" ranks the performances of the other. They showed that this kind of setup can get stuck in mediocre stable states. Indeed, competition may just lead to teachers modifying their content to get good ratings from students. As a consequence, they do well in the competitive environment imposed upon them, but do poorly at fulfilling the wider social goal of producing bright students. This, of course, would be completely contra-productive.

A solution to this problem would be to introduce performance criteria which measure how well teachers reach the main goal – that is, enabling their students to succeed in their further education, and maybe also on the mid- and longer term, that is, in their professional life. Students and their parents would certainly understand that it makes sense to choose a teacher which assures the further academic and/or professional success of their students as opposed to providing good entertainment (although both is relevant for efficient learning).

**Performance evaluations:** An important aspect of the educational system is that it needs to evaluate students. The typically used large scale standard tests fail to thoroughly reflect on people's capabilities and skills. Classical school knowledge cannot be equaled to success in life; very good students may fail in life, whereas weak students may gloriously succeed. Society needs people with a great diversity of individual skills, knowledge and characteristics, including manual skills, emotional intelligence, the ability to collaborate in teams, etc. Often, the required skills and knowledge do not correspond to classical school disciplines, and are thus badly reflected by standard examinations in those disciplines.

An alternative and more sensible way of assessing students may be so-called "portfolio assessment", meaning that not only single written exams count, but also individual and group projects, self-motivated studies, applications scenarios, and other studies. Typical arguments of educational institutions against such forms of assessment is, for instance, that it is more challenging to define success criteria, and that these assessment forms require more human resources, which are often scarce due to financial pressures.

Moreover, not only the standard skills which everybody needs must be assessed, but also and especially the particular skills needed for particular activities. This is called "niche selection" in biology, and it means comparing similar students with each other. The assessment of "non-classical" skills is not straight forward but well worth the effort of elaborating useful metrics.

Yet another aspect of introducing competition and mutual selection to the educational system is that not only students need to be evaluated, but also teachers, respectively the quality of their teaching. This is difficult because there is a lack of real comparison possibilities: it is impossible to test the same students on the same topic, using a different teaching method / a different teacher. Further efforts to find ways of evaluating teachers and teaching are required, in particular related to the issue of "deceptive goals" discussed in the subsection above.

### Case study: Switzerland

In general, Switzerland and the Swiss educational system are doing very well. Although the country has very few

natural resources, the economy is fairly stable and hardly affected by economic crises. The unemployment rate has for many years remained around 3.5 - 4%, which is very low in comparison with other countries. Switzerland faces high amounts of immigration, and its population currently consists of 22% of foreigners, speaking many different languages in addition to the 4 official languages. Nevertheless, the difficulties surging in the educational system are well coped with. Given that many of the actions recommended by the complex systems approach – for instance having high diversity at the right levels – are already implemented in Switzerland and that the systems works well, we can conclude that the approach is valid. A few problems, however, persist in the educational system, and we will look at them subsequently.

Switzerland has a highly diverse educational system which is in many aspects governed by what we call the “Kantönligeist” – the spirit of the little cantons (of which small Switzerland has 26!) – which means that every canton can autonomously decide about their school system. This fragmented attitude is due to the nature of the Swiss state, which is a federation, and due to the populations appreciation of old ways and traditions; conservatism prevails.

Remarkably, the country has almost exclusively public schools, and they generally are of high quality – as just about everything in Switzerland; the few private schools have particular characteristics as following Rudolf Steiner’s teachings or being international / foreign.

One of the strongest points of the Swiss educational system is that many ways lead through education to profession; some of the ways focus on academic achievements, others provide solid manual and profession-specific training. Details are given in the next subsection, followed by an analysis of the Swiss educational system and recommendations derived from the complex systems approach as introduced earlier in this paper.

## Ways to professions in Switzerland

As illustrated in Figure 2, children enter the educational system at the age of 4 or 5, starting with 1-2 years of the recommended but not mandatory public Kindergarten. Some private Kindergarten establishments accept children much earlier, in some cases even as early as from the age of 4 months. The mandatory nine school years start with primary school at age 6 / 7. There are diverse forms of primary school (4-6 years) and intermediary “cycles” (1-3 years under diverse names), after which the adolescents around age 13 either go to some form of secondary school. It takes about 2-3 years and comes in several levels, according to the students’ capabilities. Assessment is continuous, and there are no major final exams at the end of secondary school.

Those students which show sufficiently good performance in primary school and already know that they are headed towards university may attend the so called “Pre-gymnasium”

(2 years), which then leads to the “Gymnasium” (4 years). Several specialties are available, preparing the students for university. Assessment is continuous, and there are also major examinations at the end, called “Matura”. Succeeding them gives direct access to any university in Switzerland – except for medicine, where *numerus clausus* takes place.

For those ending their school education at age 16, there is an excellent way of acquiring well-founded professional qualifications: an “apprenticeship” is a vocational training on the job, accompanied by 1-2 days per week at a specialised professional school. Assessment is continuous and includes both practical and theoretical evaluations. The final examinations lead to a nationally recognised diploma, which is crucial for future employment. About 70% of the adolescents choose this option, which gives them a solid practical education while already receiving a small salary (which is a considerable advantage in comparison with those who are still in full-time school!). In case the young adults with professional diplomas wish to acquire further qualifications, they can either attend technical schools or top-up their education with 1-2 years of general education which leads to a “professional Matura” and gives them access to the universities of applied sciences.

Further information about the educational system in Switzerland is available on:

<http://www.swissworld.org/en/education>.

## Current state of the Swiss educational system

On the **positive** side, as mentioned before, the general state of the educational system in Switzerland is rather good. Already at primary schools, individual support tutoring is offered to students with special needs, no matter what it is: the local language, mathematics, reading, writing, keeping their attention focused, general learning skills, or something else. In some cities, senior citizens accompany school classes several days per week and provide support to teachers and students. Evaluations in most primary schools and some secondary schools include talks between child, parents and teacher for the assessment of the child’s performance and the setting of individual learning targets.

While there are national standards for education, there are also many individual ways of achieving them, based on the student’s characteristics, interests and performance. As it turns out, with this plentitude of possibilities, there really is a way for everybody to receive suitable education.

On the **negative** side, many primary school teachers complain about their massive work load, trouble with parents, too much responsibility, too many diverse objectives to achieve, and difficulties with the coordination of their students very diverse time tables which must include all their support tutoring and special lessons.

Over the last 2 decades, male teachers have become a rarity at primary schools, whereas at secondary schools, the

Approx. age	...diverse ways, ranging from manual professions to academic professions...		
4 - 6	Kindergarden (1-2 years)		
6 / 7-12	Primary school (4-6 years) (+ intermediary "cycles"), diverse names !		
13-15	Secondary school on 3 levels (2-3 years); continuous evaluations but no final examinations		"Pre-gymnasium" (2 years)
16-19	Apprenticeship / vocational training (2-4 years): training on the job + 1-2 days / week at specialised school; continuous practical and theoretical evaluations, final examination gives nationally recognised diploma ...about 70 % of people choose this option! (*)		"Gymnasium" / high school (4 years), diverse specialties; final examinations ("Matura") give university access except for medicine
	Work	Professional "Matura" (1-2 years)	...also other types of schools (nurses, teachers, business)

Figure 2: Swiss education system overview

ratio between male and female teachers is still quite equilibrated. It has not been finally determined what the reasons for this development are, but it has been suggested that it may go hand-in-hand with the declining prestige which society attributes to primary school teachers. Again, the reasons are not known, but they may well be related to the previously mentioned total absence of competition and selection possibilities.

Another difficulty which people face in the Swiss educational system are the complications that come with moving from one canton to another, which is in today's dynamic society a rather frequent necessity. The transition from one canton's educational system to another does often not go smoothly. The time when a second language of the country and English are introduced differs considerably, even from one city to another. Some insist that English should be the third language the children learn, and only address it in secondary school, while others start their "early english classes" already in the first year of primary school or even Kindergarden, and before the second language of the country. Similar inconsistencies exist also in the areas of mathematics or natural sciences.

Interestingly, the B.Sc. which the universities of applied sciences award do not provide direct access to M.Sc. studies at academic universities; conversion courses are required. Similarly, people with a classical Matura do not have direct access to the universities of applied sciences; practical experience in industry is necessary. As it is, a B.Sc. from an academic university is thus not equivalent to a B.Sc. from a university of applied sciences. These difficulties are one of the drawbacks of such a diverse system.

## Recommendations of the complex systems approach

Based on the general analysis of the different levels derived from the complex systems approach to educational systems as detailed in the fourth section – entitled "Complexity at different levels" – and the analysis of the Swiss educational system in the above subsections, the following concrete recommendations are made:

- **Micro-level / local level:** The diversity of actions and measures available for supporting the individual student already being very high, the system has sufficient complexity for addressing the diversity of needs. However, the responsibility for the students' education could be distributed over a team of teachers and experts, including psychologists; Davis and Sumara (2006) also suggest this. Forming teams would relieve the currently high pressure on individual teachers, and transfer the coordination of the task from the micro- to the meso-level.
- **Meso-level / intermediate level:** Some elements of competition and selection may both increase the prestige attributed to the teacher profession (and thus its attractiveness for male teachers) and mitigate the critical attitude of the public towards teachers. A way to introduce competition without drastically changing the school system would be to have publicly available teacher and school ratings; maybe a bonus part of the teachers' salaries could depend on their rating by students, parents and peers. Such ratings would need to include both popularity, which is related to entertainment value and freedom of choice, as well as the short-/mid-term achievement of academic

goals and mid-/longer term professional success. More important changes could be made in later steps.

Where necessary, more support for groups of immigrants could be offered. Immigrants not only need to learn the local language but should also familiarise themselves with the local culture to assure a smooth integration.

- **Macro-level / global level:** To improve the consistency of the scholar system, the cantons should finally bring themselves to agree on a common school structure. There is no objectively sensible reason to keep the differences. The HarmoS project<sup>2</sup> aims at this, and about two third of then cantons have accepted to join, but the other third sadly refused. Similarly, it is necessary to agree on when to introduce English and the second language of the country; additional languages are optional and therefore not problematic.

### Related work

The application of the complex systems approach to learning and education has been pursued by a variety of researchers mainly over the last two decades. A working group first met at the NECSI – New England Complex Systems Institute – in 1999. Kaput et al. (1999) state that their intention was to apply the complex systems approach to education in content, teaching, learning, cognition, and the educational system itself. They started by asking the plenty of questions; some answers are given by Bar-Yam (2004).

Lelouche and Morin (1997) emphasise the difference between three education-related knowledge types: knowledge about the domain and problem-solving, which are both to be acquired by the students, and tutoring knowledge, used by the system to facilitate the students' learning process. These three types are modelled at different levels of abstraction, to shed a uniforming light on the educational system's operation and performance.

Vanderstraeten (1997) studies the discrepancy between an economic perspective on the educational system, which focuses on manpower-planning / cost-benefit analysis, and a social perspective, which wishes for an educational system than satisfies the "voice of the people". Both perspectives, however, neglect the fact that education is a composition of complex circular processes between the educational system and society. Policy-makers need to take this into account when designing educational systems.

Davis and Sumara (2010) point out that learning is complex, and education is one of the most complex of human enterprises. Most complex systems are also learning systems. The authors review insights gained by researchers looking into a holistic and action-oriented complexity. Classrooms can be described as knowledge-producing networks, rather than contexts that are centered around a teacher or student.

<sup>2</sup>Information about HarmoS is available in German and French on: <http://www.edk.ch/dyn/11659.php>.

Similarly, curricula should not be seen "in terms of basics and foundations in discrete disciplines, but rather as nodes, hubs and links in decentralised networks of human knowing". Also, learning is not so much the achievement of an individual, but rather something that emerges from the participation and implication of others.

In their book, Davis and Sumara (2006) look into the importance of complexity for various aspects of education, including learning, teaching and research, and suggest complexity thinking as an appropriate attitude for people involved with education. Among other findings, they conclude that teams can considerable out-perform the sum of the team members individual actions. This is a fact which has implications for the classroom, school boards, associations, communities and societies.

Complexity and education has received an increasing amount of interest over the last few years. A rich resource about this topic is <http://www.complexityandeducation.ualberta.ca>. An annual international conference has been held since 2003 under the name of the "Complexity science and educational research conference", and a corresponding journal is published under the name of "Complicity: An International Journal of Complexity and Education".

### Discussion and conclusion

Findings from complexity science can help solve problems in man-made complex systems, including educational systems. A key point is to recognise the importance of complexity and scale at different levels, and to adapt the available instruments, tools and measures to be taken accordingly. For instance, a large scale uniform approach is ill-suited to address a problem which requires diversity at a smaller scale. On the other hand, missing standards at the global level can cause inconsistencies at lower levels and thus lead to unnecessary turbulences.

Some may argue that education is merely complicated and not complex. True, the fact that different people have different learning preferences and abilities is not specifically a complex systems idea, and is probably better described as effectively the theory of individual differences from psychology. Teachers and the educational systems must then compromise to build a system which is reasonably well-suited for most students and provides society with individuals that have the necessary skills and knowledge for society to function. However, taking the working definition (Frei, 2010) that a complex system is composed of many multi-laterally interacting individuals, where changes in one place may have consequences at another place, educational systems very well qualify as being complex. The question investigated in this paper is whether the complex systems approach may provide useful hints at how to improve educational systems, and this has been confirmed so far. Further practical investigations, however, are certainly indicated.

In the case of the Swiss educational system, the great diversity of tools and intervention possibilities at the micro-level allow the teachers and school psychologists to find a suitable approach for every child; responsibility, however, should be distributed among a team instead of being on one teacher alone. At a meso-level, groups and associations for students with similar characteristics and interests would provide support and incentives for maximising performance, both for students and teachers. At the macro-level, Switzerland has a very diverse system in two senses, with only one being helpful: the diversity of ways to a profession, including vocational education in the form of an “apprenticeship”, specialised technical schools, universities of applied sciences, and academic universities, is certainly a strength of the Swiss system and assures the high quality of professionals. On the other hand, the differences in the school systems between the cantons is rather disturbing and hinders people who move from one canton to another from advancing as desired, and more nation-wide uniformity at the macro-level would make sense.

Concrete measures to be taken to improve the educational system in Switzerland include the shifting of responsibility from individual teachers towards small teams which may include psychologists and other experts, and the agreement on a consistent education system structure across the country.

Generally speaking, for a complex adaptive system to function and cope with changing conditions and incidents, a multi-level approach with great diversity at the micro-level, many choices at the meso-level, and common standards at the macro-level is recommended.

Once the importance of complexity and scale at different levels has been recognised for the educational system, the next steps include persuading politicians and authorities in the educational system, which is quite a challenge in itself. The human reluctance to change is considerable, especially since the traditional approach was successful in the past. However, the world is changing rapidly – among others becoming increasingly connected and intertwined – and thus our approach to teaching must change, too.

## Abstract

We argue that the phenomenon of life is best understood as a process of open-ended becoming and that this potentiality for continuous change is expressed over a variety of timescales, in particular in the form of metabolism, behavior, development, and evolution. We make use of a minimal synthetic approach that attempts to model this potentiality of life in terms of simpler dissipative structures, using reaction-diffusion systems to produce models that exhibit these characteristics. An analysis of the models shows that its structures exhibit some instances of relevant changes, but we do not consider them open-ended enough to be called alive. Still, the models shed light on current debates about the origins of life, especially by highlighting the potential role of motility in metabolism-first evolution.

## Introduction – The standard view

In the field of synthetic biology there is a widespread optimism that the creation of an entire living cell from scratch is imminent (e.g. Zimmer, 2009; Deamer, 2005; Szostak, et al. 2001). It is hoped that this bio-engineering approach will help to resolve one of the outstanding mysteries of science, namely the origin of life on earth. The mainstream consensus is that the crucial element in the transition from non-living to living matter is the appearance of evolution. Many of the researchers in the field of artificial life, who are studying the origin of life, also share this guiding idea. Their work is thus focused on the question of how best to simulate or chemically engineer the emergence of self-replicating structures (e.g. Rasmussen, et al. 2004; Solé, 2009). Within this general direction of research we can distinguish two relatively distinct traditions in terms of whether they assume the replication of information or the replication of metabolism to be the first factor in evolution.

The *information-first* (a.k.a. ‘replicator-first’)<sup>1</sup> view of life claims that there was *genetic evolution* right at the start of life itself. An extreme version of this view is known as the “RNA world”, which holds that “the first stage of evolution proceeds [...] by RNA molecules performing the catalytic activities necessary to assemble themselves from a nucleotide soup” (Gilbert, 1986, p. 618). However, it is now recognized that this RNA-only view is incomplete, and that the appearance of

Darwinian evolution also requires the compartmentalization of replicating nucleic acids to ensure the segregation of genomes from one another. The field has therefore turned toward the task of incorporating suitable information-carrying molecules into the right kind of vesicle in a way that ensures the reproduction of both (e.g. Hanczyc, et al. 2003), and in a way that allows for competition and differential success (e.g. Chen, et al. 2004). On this updated information-first view, the role of metabolism in the origin of the first living cell is at most a secondary aspect, and perhaps even completely absent. Rather, the essence of life consists of only two components: “fundamentally, a cell consists of a genome, which carries information, and a membrane, which separates the genome from the external environment” (Chen, 2006: 1558).

The *metabolism-first* view of life, on the other hand, claims that the main driving force at the origin of life was *epigenetic evolution*. A radical version of this view holds that the origin of life coincided with the emergence of autocatalytic systems (e.g. Kauffman, 1986), and that under certain conditions some selective pressures could have already been effective at this chemical level (e.g. Fernando and Rowe, 2007; Meléndez-Hevia, et al. 2008). It has also been claimed that “Darwinian competitive exclusion is rooted in the chemical competitive exclusion of metabolism” (Morowitz and Smith, 2007: 58), and that metabolism has played a bigger role than replication in making novelties appear in evolution (Pulseli, et al. 2009).

Similar to the updated information-first view, many of the metabolism-first researchers also argue for the essential role of some kind of spatial separation. It is said that autocatalysis by itself is not sufficient for life, and that these processes must necessarily be part of the constitution of a spatially localized individual (Maturana and Varela, 1980). Some researchers have gone further in claiming that the network of autocatalytic processes must necessarily be enclosed within a bounding membrane (e.g. Luisi and Varela, 1989).

Modeling studies along these lines have tended to assume that a physical membrane is essential, because it prevents the autocatalytic processes from diffusing into the environment (e.g. Bourguin and Stewart, 2004; Varela, et al. 1974), and allows the regulation of molecular intake (e.g. Bitbol and Luisi, 2004). Research in prebiotic chemistry has shown that it is possible to engineer the emergence of membrane-bounded micelles that provide the autocatalysis for their own replication (e.g. Walde, et al. 1994; Bachmann, et al. 1992; see also the model by Ono and Ikegami, 2000). In addition, recent models have demonstrated that under some conditions the growth and division of membrane-bounded autocatalytic

<sup>1</sup> We call the ‘replicator-first’ tradition ‘information-first’ here in to avoid the misleading impression that the ‘metabolism-first’ tradition does not involve replication. The core of the dispute is not about replication versus emergence as such, but rather about what kind of replication was primary, namely informational versus metabolic or compositional.

systems can lead to differential replicative success (e.g. Ono, 2005; Ono, et al. 2008). On this view, which is sometimes identified with the “autopoietic” approach (e.g. Maturana and Varela, 1980; Varela, et al. 1974), the essence of life consists in a membrane-bounded, self-producing system.

It is important to notice that, although the two mainstream traditions may differ in emphasis, they do not hold mutually exclusive theories about the essence of life. In fact, they both accept the general claim that a biological individual is defined by the physical boundary that is imposed by its membrane, although they have different primary reasons for doing so (i.e. unit of selection versus unit of self-production). And they also both accept that life is essentially about stability and survival, and that the driving force of instability and biological change is primarily located outside of the individual, in the external environment and in evolutionary changes. They only disagree on the details of this account (i.e. is survival primarily about other generation or self re-generation, and is the beginning of evolution genetic or epigenetic). In general, the underlying assumption of the mainstream view is that the first form of life is essentially structurally isolated and behaviorally passive.

In this paper we will challenge this assumption. We follow Virgo (2011) in arguing that dissipative structures whose self-production is spatiotemporally localized, but not necessarily membrane-bound, have much in common with living beings. Even very simple examples of these structures are capable of motility, adaptive behavior, structural change, and epigenetic evolution. Consequently we regard such systems as worthy of study in the context of the origins of life.

### **Living without doing? An alternative view**

Despite some outstanding disagreements, the two mainstream traditions are united by a theoretical view of life that is centered on a combination of the spatiotemporal conservation of the individual with an evolutionary realization of biological change. Accordingly, there are promising attempts to bring these two traditions together, such that life is viewed as essentially consisting of three distinct and yet functionally interrelated components: an informational system, a metabolic system, and a compartment (e.g. Rasmussen, et al. 2003; Ganti, 1975). And given this convergence of the two main traditions, and considering the recent experimental successes in realizing this view via synthetic biology, it seems that the optimism pervading the field is well founded. The creation of all kinds of useful artificial life forms appears to be within our grasp, and the final mysteries of the origin and evolution of life on earth seem tantalizingly close to being resolved.

However, the confident promises of synthetic biology will sound all too familiar to those of us who know the history of synthetic psychology – an approach better known as artificial intelligence. Indeed, around half a century ago there was a similar optimism prevalent in the scientific community that the creation of artificial minds and conscious robots was just around the corner. The driving force of that optimism, which in hindsight looks hopelessly naïve and deeply misguided, was a digital-information-centered science of the mind that resonated with advances in engineering and technology.

Today the view that cognitive science can be reduced to computer science is no longer in fashion, although the alternative still remains to be properly worked out (Froese 2010). How ironic it is, then, that at the moment in which

cognitive science is undergoing a major theoretical makeover, namely toward a view of the mind as essentially embodied, embedded, and enactive (e.g. Gallagher 2005; Clark 2008; Thompson 2007), the science of life is at the same time extolling the virtues of trying to reduce the complexities of cellular biology to the abstract linearity of “logic circuits” (Nurse 2008) and “computer programming” (Balazs & Epstein 2009). History, it seems, is repeating itself.

But the purported reduction of life to logic is not as straightforward as the recent advances in biotechnology may seem to indicate. In particular, we note that, in a crucial sense, the life of the individual organism is completely absent from the mainstream framework outlined above. On the one hand we have structural self-maintenance, and on other hand we have informational self-replication. However, we know the former from the general class of dissipative structures, and the latter from the case of viruses – and neither of these two phenomena is typically considered as being alive. What they are missing is the autonomous expression of goal-directed behavior at the level of the individual, namely forms of translational movement and transformational change, which can be studied in terms of ethology and ontogeny.

We propose that all of these aspects of life, i.e. metabolism, behavior, development, and evolution, are integrated into one coherent process of open-ended becoming. On this view, the possibility of distinguishing between these different aspects is simply due to the fact that the process of living is expressed in terms of activities on a variety of timescales. All known forms of life are embedded within four broad categories of change:

Metabolism: the events on this timescale are taking place continuously in the chemical domain. They are foundational in that they realize the concrete, spatiotemporally localized, existence of the individual living being in an autonomous manner via self-production (Barandiaran and Moreno, 2008).

Behavior: the events on this timescale are unfolding in the relational domain of the individual-environment interaction in a moment-to-moment manner. The relational changes can be more or less tightly coupled to metabolic changes (Egbert, et al. 2010), but they are a non-reducible emergent property of the interaction that cannot be conceptualized non-relationally.

Development: events on this timescale make an individual become a structurally qualitatively different kind of individual within its lifetime. Examples are learning and morphogenesis.

Evolution: structurally qualitative changes in the historical lineage of generations of individuals take place on even larger timescales. Examples are genetic, compositional genetic, and epigenetic forms of evolution that are shaped by natural selection, sexual selection, and/or natural drift.

Of course, the differentiation of the changes exhibited by living beings into these four distinct timescales should not be misunderstood in any absolute sense. Our starting point is to treat life as a unified phenomenon, and these distinctions do not reflect strict boundaries between the distinct timescales of becoming. While each of these timescales can be addressed in relative isolation, as demonstrated by their respective fields of scientific study: molecular biology, ethology, developmental biology, and evolutionary biology, a complete understanding of life must be able to show how these different aspects are expressions of one and the same unified phenomenon. They are mutually interdependent and yet non-reducible.

We suggest that one way of approaching this issue is by introducing the intermediate timescales, namely behavior and development, into the current debates surrounding the origin of life. We need to consider that the living ‘self’ referred to by the notions of self-maintenance and self-replication is a center of activity, i.e. an agent (Ruiz-Mirazo, et al. 2010). And at the same time this additional complexity requires a model that is simple enough so that it can still be understood in a complete manner. To be sure, it may be that the most minimal form of life that satisfies our timescale criteria would actually have to be a membrane-bound single-celled organism that is already capable of information-based genetic evolution by means of natural selection. This is, of course, the hope that is harbored by those in synthetic biology who are trying to create life by combining bounded self-maintenance with self-replication.

On the other hand, we know from work in artificial life that some life-like behaviors can already be found in protocells and prebiotic chemistry. For instance, it has been shown that metabolic self-production can easily lead to movement as well as adaptive gradient following, i.e. chemotaxis, in minimal models of protocells (e.g. Suzuki and Ikegami, 2009; Egbert, et al. 2010). Similarly, it has been demonstrated that some of the chemicals typically favored for the synthesis of artificial cells can spontaneously form oil droplets that exhibit self-sustained motility and a type of chemotaxis (e.g. Hanczyc, et al. 2007; Toyota, et al. 2009). It is in this context that there have been calls for the establishment of a new field of study, variously labeled as “homeodynamics” (Ikegami and Suzuki, 2008), “chemo-ethology” (Egbert and Di Paolo, 2009), and “chemical cognition” (Hanczyc and Ikegami, 2010). In what follows we make a novel contribution to this endeavor.

## The primacy of movement

Let us conclude this introduction by outlining our motivation for the rest of this paper. It has been argued that the ‘RNA world’ hypothesis faces considerable difficulties when confronted with the constraints of prebiotic Earth (Shapiro, 2000). One promising response is to reject the requirement of a *digital* genetic system for open-ended evolution, and to relax the distinction between genotype and phenotype. It is possible that these two features may not have been present at the origin of life, but developed in later stages. We therefore assume that a primordial protocell’s chemical mixture itself can serve as a kind of “compositional genome” (Segré, et al. 2000), which remains relatively well preserved during protocell division; or alternatively that heredity can be achieved through multiple attractors in the autocatalytic reaction network’s dynamics, as in the model of Fernando and Rowe (2007).

We could also assume the existence of a self-organizing membrane structure to protect the consistency of the chemical mixture from adverse environmental influences, e.g. a lipid vesicle (Luisi, et al. 1999). This is the main alternative “Lipid world” scenario of the origin of life (Segré, et al. 2001). However, through this additional step the scenario inherits the major underlying assumptions of the standard view, namely that the origin of life gave rise to an essentially structurally *isolated* and behaviorally *passive* entity. The living individual is enclosed in an interactionally inert compartment. And yet all life as we know it today is an active process of organism-environment interaction and its adaptive regulation (Di Paolo, 2009), and the membrane of cellular organisms is an active

interface in this process (Hanczyc and Ikegami, 2010). It is precisely by means of this active self-other interface that a cell regulates its metabolism and behavior through chemical and sensorimotor coupling (Bitbol and Luisi, 2004).

This dilemma leaves us with two possibilities: either we continue to assume that life began enclosed in a compartment and try to explain how this boundary later developed an active role, or we relax the traditional requirement of a compartment as the first step in biological organization (Tanford, 1978). It may seem that only a structural compartment can ensure the individuality of a protocell as an entity that is distinct from its environment, but this is not always the case. This assumption confuses the organizational limits of the organism with its spatial boundaries (Virgo, et al. 2011). It is possible that chemical gradients are sufficient for the self-maintenance of a coherent systemic identity, as we will argue below.

While it is true that such a flexible ‘boundary’ makes it more challenging to survive in unfavorable environmental conditions, it is also the case that some adverse effects of the environment can be mitigated by rapid multiplication and, especially, by motility and directed exploration – a possibility that has not yet been sufficiently considered by the standard view. Here we see the importance of distinguishing between different timescales. In other words, in evolutionary terms it does not matter if these individuals are more prone to die from environmental events, as long as they can replicate and move to different areas quickly enough. The whole population must be sufficiently distributed in space such that some of them always remain alive. It is therefore conceivable that at the origin of life a capacity for adaptive self-motility came before the development of a more solid self-boundary. The model described in the next section is intended as a minimal proof of concept of this possibility.

## Toward a Minimal Model of Life

One of us (Virgo, 2011) has argued that many of the properties of living organisms are shared by simple dissipative structures of the kind that form in reaction-diffusion systems. Prigogine (1955) coined the phrase “dissipative structure” to denote a structure within a physical system that is actively maintained by a flow of energy and/or matter, rather than being an inert structure that is merely resistant to decay. Prigogine observed that living organisms are dissipative structures in this sense; however there are many other examples.

Given what has been argued above, a suitable starting point for our model would be a self-sustaining chemical processes that is a spatiotemporally coherent individual, and yet is non-compartmentalized. These criteria are met by a special class of dissipative structures, which Virgo (2011, Chap. 5) has called *precarious, individuated dissipative structures*. In addition to being dissipative structures, organisms have the properties of being *precarious*, in the sense that if their structure is sufficiently disrupted it will stop being maintained (i.e. death); and *individuated*, in the sense that organisms are spatially localized, and this localization is a result of the dissipative processes that make up the organism, rather than being imposed from outside (see also Di Paolo, 2009).

Virgo points out that certain other dissipative structures share these properties with living organisms. One non-living

example of this type is a hurricane (McGregor and Virgo, 2009). It is dissipative in that it ‘feeds’ off a temperature gradient between the sea surface in the upper atmosphere; it is precarious in that if an important component is removed it can blow out (as will eventually occur if it passes over land); and it is individuated in that it is the cause of its own spatial localization. Not all dissipative structures are precarious or individuated, and not all precarious, individuated dissipative structures share all properties of living systems. Nevertheless, as Virgo argues, studying such structures provides a useful methodology for modeling some of life’s basic properties.

A simple and easy-to-study system that exhibits precarious, individuated dissipative structures is the Gray-Scott reaction-diffusion system, which was first studied in a two-dimensional context by Pearson (1993). This is a simple model of chemical reactions taking place on a surface. The reaction modeled is a simple autocatalytic one,  $A + 2B \rightarrow 3B$ , meaning that when two molecules of  $B$  collide with one of  $A$ , they react to produce a third molecule of  $B$ . A second reaction,  $B \rightarrow P$ , represents the decay of the autocatalyst into an inert product that leaves the system. The molecules  $A$  and  $B$  have a separate concentration at each point on a 2-D surface, represented by  $a$  and  $b$  (the concentration of  $P$  is not modeled). In addition, the ‘food’ molecule  $B$  is fed into every point at a rate proportional to  $1-a$ . This can be thought of as due to the surface being immersed in a solution of  $A$  at a constant concentration of 1.

Finally, in addition to reacting and being added to the system, the two chemical species can diffuse across the surface. Overall this gives rise to the equations

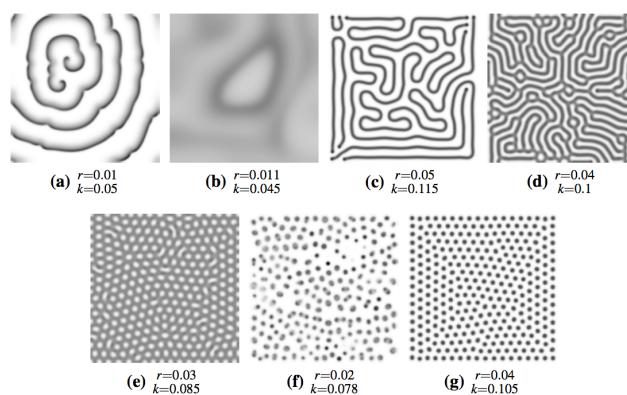

$$\frac{\partial a}{\partial t} = D_A \nabla^2 a - ab^2 + r(1-a); \quad (1)$$

$$\frac{\partial b}{\partial t} = D_B \nabla^2 b + ab^2 - kb, \quad (2)$$

where  $a$  and  $b$  are functions of space as well as time,  $r$  and  $k$  are parameters determined by the rates of the two reactions and the feed process (the rate of the autocatalytic reaction has been set to 1 without loss of generality), and  $D_A$  and  $D_B$  are the rates at which the species diffuse across the surface. These equations can be solved numerically using a method that is akin to a cellular automaton, except that each cell contains a continually variable amount of the two chemical species.

Pearson observed that, depending on the choice of initial parameters, this system can form a variety of patterns, some of which are shown in Figure 1. Of particular interest are the spot patterns in Figure 1(f) and 1(g), since the spots have the properties of being individuated and precarious (Virgo 2011).

Finally, we know that many kinds of dissipative structures that are formed by reaction-diffusion systems are also capable of sustained movement and even replication. This kind of self-organized motility has been investigated experimentally (e.g. Lee and Swinney, 1995; Lee, et al. 1993; 1994) and modeled mathematically (e.g. Varea, et al. 2007; Krischer and Mikhailov, 1994; Pearson 1993). The dynamics of replicating reaction-diffusion patterns have also been studied (e.g. Reynolds, et al. 1994; 1997). In the dissipative structures of the Gray-Scott model we find cases of motility and replication as well, and this includes some kinds of spots. We thus have all the basic requirements to begin our investigation of these spots as a potential minimal model of life as a form of open-

ended becoming, as it is expressed on the four timescales of metabolism, behavior, development, and evolution.

**Figure 1.** Examples showing the range of patterns exhibited by the Gray-Scott reaction-diffusion system with various parameters ( $D_A = 2 \times 10^{-5}$  and  $D_B = 10^{-5}$  in each). The integration method and initial conditions are similar to those used by Pearson (1993). Patterns are chosen as exemplars of various phenomena; see Pearson (1993) for a more systematic classification. (a) A spiral pattern; (b) A chaotic pattern of travelling waves; (c) A line pattern. Lines grow at the ends and then bend to fill space in a process reminiscent of a river meandering; (d) A labyrinth pattern; (e) A hole pattern; (f) A pattern of unstable spots, whose population is maintained by a balance between reproduction and natural disintegration; (g) A stable spot pattern. Spots reproduce to fill the space and then slowly migrate into the more-or-less organized pattern shown (with a different choice of parameters, spots can be produced that are stable but cannot reproduce).

## Metabolism

A reaction-diffusion spot can spontaneously emerge under appropriate conditions, and once it exists, it can self-maintain its precarious existence by means of a continuous turnover of chemical reactions. As a self-producing network of chemical processes it satisfies the requirements of the first timescale. It also provides the reference point of a spatiotemporal entity against which changes on other timescales can be measured.

It is interesting to note in this regard that the spatiotemporal boundaries of a spot are intrinsically fuzzy. It is just as impossible to pinpoint the precise moment in time when the spot begins or ceases to exist, as the precise point in space where the spot ends and the environment begins. This is because the spot is a self-organizing phenomenon that is both continuous in time (temporal ambiguity) and continuous in space (spatial ambiguity). Nevertheless, an intuitive grasp of what constitutes an individual spot is possible; we either see an individual spot on the surface or we do not.

Once an individual spot has spontaneously formed, it will continue to exist even when it encounters a limited range of conditions that would not have enabled its original emergence. The fact that spots can exist outside of their original range of emergence is an indication that they are actively re-producing the viability conditions required for their existence, which can be considered as a strong criterion for autopoietic autonomy

(Froese and Stewart, 2010). It is no different in the case of living beings: although they must have first emerged when the environmental conditions were right, they must now actively produce their own conditions of existence in order to persist.

## Behavior

We define the concept of behavior broadly as any change in the individual-environment relationship, which is induced by an instability or tension in that relationship. A behavior ceases when that tension is resolved or transformed into a different kind of tension, which elicits a different kind of behavior. In this paper we take the view that all behavior is characterized by an essential asymmetry centered on the individual (Barandiaran, et al. 2009). The tension that triggers a behavior may originate in the environment, but the fact that there is a response at all is an achievement of the self-constitution of the individual. In this sense their behavior is intrinsically active.

The term ‘behavior’ covers a huge variety of changes in all kinds of entity-environment relations, so some distinctions are in order. One important distinction in biology and psychology is between *reactive behavior*, namely behavior that is triggered by events in the environment, and *active*, or *intrinsic behavior*, namely behavior that is initiated by the individual. Again, the distinction is not an absolute one since, on the one hand, all biological systems have internal state and their reactive behavior is therefore always also a function of their history, and, on the other hand, the expression of active behavior always takes place in the context of environmental events. Nevertheless, a behavior can be more or less driven by autonomous and environmental conditions. Let us consider these two kinds of behaviors in the case of the spots.

**Reactive behavior.** The spots exhibit a clear type of reactive behavior with respect to differences in chemical gradients in their surroundings. We can describe this behavior in terms of approach and avoidance: the spots are capable of following chemical gradients that increase the concentration of their constituents, i.e. chemotaxis, and they are also capable of avoiding chemical gradients that decrease the concentration of their constituents. For example, when we remove constituents from nearby a spot by using a virtual pipette, the spot will tend to move away from the pipette. In this way it is possible to chase spots around the surface. If the pipette is too fast and gets too close to a spot, it destabilizes the spot in such a way that it is no longer sustainable and dies.

If there are several spots in the environment, then these approach and avoidance behaviors will make them interact in certain ways. This is because a spot consumes the food in its proximity, thereby surrounding itself with a negative gradient that keeps other spots away. If the spots did not tend to move away from one another then they would merge rather than remaining separate; these approach and avoidance behaviors therefore form an important part of the individuation process.

Note that although these behaviors are reactive in the sense that they do not occur except in the presence of an appropriate environmental trigger, they are the result of an active growth process. The spot moves because the autocatalyst grows faster on the side where the food concentration is higher. This behavior could thus be said to be reactive in the behavioral domain, but active in the metabolic domain. In order for the spot to move even in the absence of environmental triggers it

**Figure 2.** Two snapshots of the system resulting from Equations (4)-(6), integrated on a surface of 2 by 2 units, with the parameters  $D_A = 2 \times 10^{-5}$ ,  $D_B = 10^{-5}$ ,  $D_C = 10^{-6}$ ,  $r = 0.0347$ ,  $k_1 = 0.2$ ,  $k_2 = 0.8$  and  $k_3 = 0.005$ . The colors are adjusted so that the secondary autocatalyst  $C$  appears as a darker shade of gray than the primary autocatalyst  $B$ . A group of spots with tails can be seen on the mid-left side of plot (a), and after duplication in plot (b) in the same place. Some tail-less spots can be seen as well, their tails having been lost in the process (hence, this is limited heredity with variation). The spots with tails move constantly in the direction facing away from their tails at a rate of approximately  $4 \times 10^{-4}$  distance units per time unit, which results in their colonizing the empty part of space more rapidly than the tail-less spots. However, with this choice of parameters, the tailed spots cannot invade areas occupied by tail-less spots, and they are eventually crowded out and become extinct.

must create its own instabilities. Of course, the whole spot is already in a far-from-equilibrium state, but what is needed is an asymmetrical distribution in the general field of individual-environment relationships (Matsuno, et al. 2007).

**Intrinsic behavior.** One way of achieving active motion is by modifying the original Gray-Scott reaction-diffusion system by introducing a second autocatalyst to the system, which feeds not on the ‘food’ molecule but on the other autocatalyst (see Virgo, 2011). That is, the reactions  $B + 2C \rightarrow 3C$  and  $C \rightarrow P$  are added to the system, so that Equations 1 and 2 are extended to Equations 4-6, where  $D_C$  is the rate of diffusion of  $C$ , and  $k_1$ ,  $k_2$  and  $k_3$  are the rate constants for the reactions  $B \rightarrow P$ ,  $B + 2C \rightarrow 3C$  and  $C \rightarrow P$ , respectively.

$$\frac{\partial a}{\partial t} = D_A \nabla^2 a - ab^2 + r(1 - a); \quad (4)$$

$$\frac{\partial b}{\partial t} = D_B \nabla^2 b + ab^2 - k_1 b - k_2 bc^2; \quad (5)$$

$$\frac{\partial c}{\partial t} = D_C \nabla^2 c + k_2 bc^2 - k_3 c, \quad (6)$$

With an appropriate choice of parameters, the effect of this is to produce spots of the primary autocatalyst, which are accompanied by a region of the secondary autocatalyst. Since the secondary autocatalyst feeds on the primary one, the spot of primary autocatalyst tends to avoid it by moving away, while the secondary spot follows. This gives the secondary autocatalyst the appearance of being attached as a ‘tail’ behind the primary spot (see Figure 2.) The spot-tail system as a whole moves around spontaneously even in a homogeneous

environment. In the sense that this motility depends on the internal constitution of the whole spot-tail system itself, we can characterize it as intrinsic rather than as reactive.

Although this spot-tail system is not strictly speaking an autocatalytic “hypercycle” (Eigen 1971), because the catalytic dependency is not mutual, it nevertheless can be considered as symbiotic to some extent (see Lee, et al. 1997). While the tail is somewhat parasitic on the primary spot (since it contributes nothing to it metabolically), their jointly induced movements can be adaptive in some environments. Thus, in contrast to the standard view that parasitic reactions are a significant problem for the metabolism-first approach because of their detrimental metabolic effects (and hence, the necessity of a compartment, see Takeuchi and Hogeweg, 2009), we argue that this is not always the case. With certain parameter settings, the spot-tail systems can reproduce more rapidly than spots without tails, and their movement also tends to make them colonize new areas more rapidly. This highlights once more the importance of distinguishing between different timescales: what may be detrimental on the metabolic timescale (parasitic reaction), can induce changes on the behavioral timescale (exploratory behavior), which are adaptive on the evolutionary timescale. Figure 3 shows an example of a scenario where over longer timescales spots with tails are better adapted than tail-less spots. The parasite-enabled exploratory behavior helps to prevent the occasional localized extinction events from killing the population. We will return to this finding later.

## Development

We conceive of the notion of development in a broad way so as to include any structural changes induced by the organism, which turn it into a qualitatively different kind of being in its own lifetime. These structural changes can include (in order of increasing temporal scale) growth, habituation, learning, adaptation, and ontogeny. Not all forms of life will exhibit all of these variations of becoming to the same extent, but all will display some capacity for developmental change.

We find lifetime dependent structural changes in the case of the spots as well. These changes typically proceed via the incorporation of external elements rather than the internal differentiation that is familiar from modern cells, but we can perhaps still think of this as a kind of proto-development. The emergence of spot-tail systems that was described above is one example. Virgo (2011) also observed a second, related kind of process in a reaction-diffusion system (with a different set of equations), whereby two nearby spots consisting of mutually complementary catalytic reactions join together to form a multi-spot system, thus forming a proper hypercycle (Eigen, 1971). In some respects, development can be seen in single spots as well. When they exhibit directional movement, they do it because they grow toward the increasing gradient, and die back on the other side. They are like plants in that growth and behavior are not always readily separable.

## Evolution

We have already observed that there is a heritable difference between a spot with a tail and a spot without tail (see Figure 2). However they are clearly lacking a digital genetic system with which to encode these differences. In our analysis of the evolutionary capacity of the reaction-diffusion systems we

**Figure 3.** A snapshot from the same system shown in Figure 2, with the same parameters, except that randomly chosen areas in the right-hand side of the surface are occasionally cleared by an externally induced cataclysm (e.g. the food concentration in a random 0.5-by-0.5 area is set to zero every 1000 time units). The spots with tails are able to persist in this region due to their ability to colonize the cleared areas more rapidly than the spots without tails. But in the left-hand side of the figure they are out-competed.

therefore focus only on the possibilities of epigenetic evolution and of evolution with a compositional genome.

**Epigenetic evolution.** It is well known that one of the main epigenetic factors of inheritance is the particular time-space configuration in which an individual is born. A famous case is the beaver's dam, which, once constructed, provides a home for subsequent generations. This kind of inheritance can also occur in the case of reaction-diffusion spots. For instance, the offspring of those spots, which happened to divide because of a high concentration of nutrients, will also find themselves in a situation with high concentration of nutrients.

**Composition-genomic evolution.** We have noted above that the chemical composition of spot can be considered as both its phenotype and genotype combined. The idea is that this kind of ‘compositional genome’ could have enabled protocellular evolution by means of natural selection even in the absence of a digital information-carrying component such as RNA and DNA (Segre and Lancet 2000). For instance, Virgo (2011) has observed spots undergoing a Lamarckian form of evolution, whereby traits that have been acquired during an individual's lifetime are passed along to the offspring. This is the case for spots with tails. Once a spot has acquired a tail (perhaps by passing near to another tailed spot), it will divide in a way that typically results in offspring that have tails.

We also find a difference in selective pressure since in some environments the spots with tails are more viable than the single spots on their own (see Figure 3). This is because their combination results in an internal instability that makes the spot system move around even in the absence of chemical gradients, and they are thereby able to minimize the impact of catastrophic events. Greater spatial distribution lessens overall risk to the population. In this scenario the original single-spot constituents may therefore die out eventually, while the spot-tail variant persists. Here we therefore have all the elements of evolution as it is standardly conceived, namely reproduction, variance, and selection, but with limited rather than unlimited heredity (*sensu* Szathmary and Maynard Smith, 1997).

## Discussion

The model has served as a proof of concept that even simple reaction-diffusion spots can exhibit many essential life-like characteristics, where life is conceived as a process of open-ended becoming. We have focused on the importance of self-organized motility and behavior in the context of current debates on the origin of life. In this discussion we would like to draw attention to the shortcomings of the current model, and to consider possible ways of overcoming them.

The spots satisfied the basic requirements of metabolism (self-creation) and movement (self-motility). In fact, they are even capable of adaptive behavior that resembles the foraging behavior of actual bacteria (nutrient gradient following). The spots are also capable of some proto-development through the incorporation of new external elements, and these lifetime changes are inheritable over generations. Taken together these findings suggest that the spots meet the criteria of undergoing changes within the four major timescales characteristic of life, namely metabolism, behavior, development, and evolution.

But are these spots a model of the phenomenon of life? We characterized life as an open-ended process of becoming, and it is precisely in relation to open-endedness that the limitations of the model are most apparent. How far can this approach be scaled up? Are compositional genomes capable of “unlimited heredity” (Szathmary and Maynard Smith, 1997) as suggested by the work of Segre and Lancet? Is it possible to set up the environmental conditions such that a more complex network of dissipative structures emerges? By which mechanism could such a network learn? How could it reproduce itself?

One issue that would need to be tackled in future models of this kind is how to introduce the possibility of solidity. In the current model the spots are fully transparent to environmental interactions, although chemical gradients may constitute some boundaries. This extreme openness effectively turns the whole spot into an interface with its environment. In order to enable a more open-ended increase of complexity it may eventually become necessary for the system to localize these interfaces at its spatial boundaries. Some researchers have argued that internal differentiation between the constitutive elements that are responsible for self-creation and those that are needed for interaction is a first step toward more behavioral autonomy (Barandiaran and Moreno, 2008). Internal differentiation may enable further specialization of these elements, since they no longer need to do both tasks at the same time.

Relatedly, it is possible that at some point a differentiation between phenotype and genotype may become necessary in order for further evolutionary transformations to become a stable possibility. And even during the organism's lifetime the internal mediation between phenotype and genotype entails a certain lack of self-coincidence in the being of the organism that could facilitate open-ended becoming. The organism's being is then no longer simply a product of its own doing, as it is in the case of the spots, but also of its own genetic self-interpretation. This is because the same DNA can give rise to different expressions in the context of a different phenotype. It is of general interest to further determine to what extent DNA is necessary for the phenomenon of life. One way to address this issue, and which we have pursued in this paper, is to see how far it is possible to get without DNA or any other genetic system. By following this approach some constraints may

become apparent for which a dedicated digital genetic system is an essential part of the solution.

## Conclusion

We have argued that the phenomenon of life is a process of open-ended becoming, and that contemporary debates about the origins of life should take the role of self-organized motility and behavior into account. We revisited Virgo's (2011) arguments concerning simple dissipative structures in reaction-diffusion systems from this theoretical perspective, and discussed the potential of some of these structures as a minimal model of life. We conclude that the current model is able to partially satisfy the proposed view by exhibiting some changes on the temporal scales of metabolism, behavior, development, and evolution. The model also demonstrated the importance of distinguishing between the organizational limits of the organism and its spatial boundaries, as well as between its various timescales. Future work should try to determine to what extent this approach is able to scale up to more complex phenomena, including individuals that have the potential for a greater variety of becoming.

## Abstract

Cross-feeding interactions are a common feature of many microbial systems, such as colonies of *E. coli* grown on a single limiting resource. We have studied this phenomenon in Gerlee and Lundh (2010) from an abstract point of view by considering artificial organisms which metabolise binary strings from a shared environment. The organisms are represented as simple cellular automaton rules and the analog of energy in the system is an approximation of the Shannon entropy of the binary strings. Only organisms which increase the entropy of the transformed strings are allowed to replicate. This system exhibits a large degree of species diversity, which increases when the flow of binary strings into the system is reduced.

## Introduction

The origin of biodiversity has been a long standing problem in ecology and the evolution and maintenance of diversity was long difficult to account for, especially in the light of the proposed competitive exclusion principle which states that several species competing for the same resources cannot co-exist. Related to these issues is the question of how species diversity influences ecosystem productivity (Waide et al., 1999). Several experiments and theoretical models have been devised to resolve this issue, but many of the results have been inconclusive and even contradictory.

One of the simplest ecological system where diversity emerges, and is stably maintained, is in populations of *E. coli* growing in a homogeneous environment limited by a single resource, usually glucose. The diversity is facilitated by cross-feeding (syntrophy), where one strain partially degrades the limiting resource into a secondary metabolite which is then utilised by a second strain. This phenomenon was first observed by Helling et al. (1987).

In Gerlee and Lundh (2010), we present a more general model of the evolution of cross-feeding, which is not aimed at modelling a specific biological system, but rather extracts and models the general principles governing systems where cross-feeding might emerge. In order to do this, we have devised a novel Artificial Life system, named *Urdar*<sup>1</sup> in which

<sup>1</sup>Urdarbrunnr is one of the three wells that lie beneath the world

Figure 1: A schematic view of the model. The agents  $a$  in the model digest binary strings  $r$  by applying CA-rules, transforming  $r$  to  $r'$ . To each such metabolic step we can associate a difference in energy  $\Delta E$  (visualised with dotted lines). The reproduction of each agent depends on how much it can decrease the energy of the binary string and occurs with probability  $P(\Delta E)$  (represented by the arrows on the left hand side). The binary strings exist in a common pool which they enter (and leave) at a rate  $\gamma$ , as shown by the arrows on the right hand side.

the fitness of an organisms is defined in a more general sense and where interactions between organisms are at the core of the model. The fitness of the organisms in this model is directly related to their ability to extract energy from a common environment, and is thus closely connected to the fundamental concept of energy which drives many ecological interactions.

Figure 2: The Shannon diversity index of the species distribution as a function of the flow rate  $\gamma$ . Each data point was averaged over 20 simulations and the error bars represent one standard deviation.

### The Model

In order to give a short description<sup>2</sup> let us give its main features. The dynamics, depicted schematically in figure 1, during one update can be described in the following way:

1. Each agent in the population picks randomly a resource string  $r_j$  from the resource pool  $R$  and transform it accordingly to its CA-rule and then puts the transformed string back into the resource pool.
2. The efficiency of the “metabolic process” just occurred is evaluated by measuring the energy difference  $\Delta E$  of the string before and after the “digestion/transformation”. This is done by drawing a random number  $x$  uniformly between 0 and 1, and if  $P(\Delta E) > x$  the agent reproduces, replacing a randomly picked agent with a copy of itself.
3. With probability  $\mu$  the offspring will be mutated uniformly to another CA-rule.
4. In order to keep energy flowing into the system, after all agents have been updated, a fraction  $\gamma$  of the strings are replaced with high energy binary strings.

### Results

The main result indicates that the diversity increases as the resource level in the system drops, and this trend was investigated systematically by measuring the time average of the Shannon index shown in figure 2 and reveals that the diversity is a decreasing function of the flow and exhibits an approximately linear decrease with the flow rate  $\gamma$ , except for a saturation for high values of  $\gamma$ .

We have also studied the total population’s productivity. See figure 3. A still open question for future studies is how

tree Yggdrasil in Norse mythology. The name means well of fate.

<sup>2</sup>An online version of the platform is available at: <http://www.math.chalmers.se/~torbjrn/Urda/urda.html>

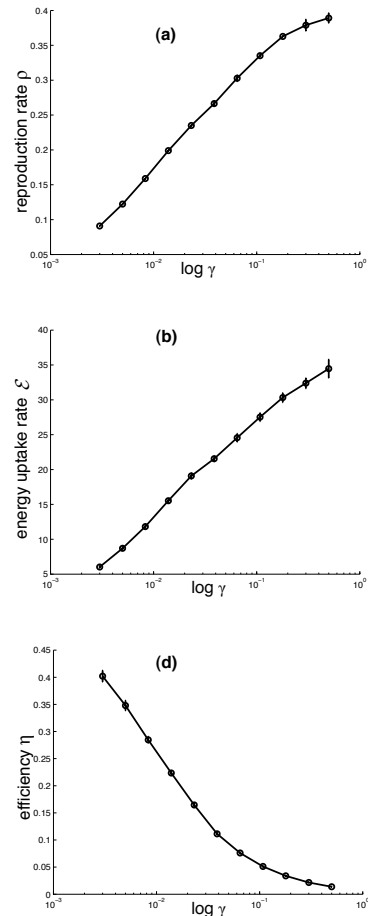

Figure 3: Three different measures related to productivity in the system. (a) shows the reproduction rate  $\rho$ , i.e. the number of divisions per update which corresponds to biomass growth, (b) shows the energy uptake rate  $\mathcal{E}$ , i.e. the energy difference between outflow and inflow, and (d) shows the efficiency of the energy uptake  $\eta$ .

good these population-productivity is compared to the optimal productivity, i.e. how good is the through evolution obtained population with respect to the total energy extraction.

## Abstract

A challenge in reproducing life is to reproduce cognition. We propose a methodology by which human actions are analyzed in a real-setting and are then used to evolve artificial neural networks capable of reproducing these actions. It is also demonstrated that analyzing human actions can be used for skill-assessment, where we introduce a model for in-silico computational psychology to assess skills and competency of human plays. The same methodologies can be used by coaches and mentors to diagnose skills for their players and juniors in an attempt to improve their abilities. Results demonstrate interesting patterns in the way expert players develop their skills overtime and that it is possible to reproduce these skills in an artificial context.

## Introduction

Establishing a methodology to analyze human actions has a wide spectrum of applications for ALife research. Understanding how human develop their expertise overtime can shed more light in the black-box of human intelligence. In this paper, we look at the dynamics of learning in real human, how skills develop and how the trajectory of skill-development for a human playing a complex game can be assessed. We use these findings to guide the evolution of artificial neural networks to play similarly to the human.

In an early paper in the ALife field, Stewart (1992) argued that life is cognition, that our knowledge and the way we make decisions are particularly crucial determinants for how we evolved. As was put by Varela (1995):

Yet when it comes to a re-understanding of knowledge and cognition I find that the best expression to the use for our tradition is abstract: Nothing characterizes better the units of knowledge that are deemed most natural.

Many studies focused on understanding the dynamics of learning and evolution (Floreano and Urzelai, 1998). In this paper, we analyze learning based on real human and map it to an artificial model.

In this paper, we consider the game of GO as an example where a human player needs to start from the lowest skill level, working his/her way up to establish themselves as advanced players. We needed to select a gaming environment in general and the game of GO in particular as our test platform for a number of reasons. The beauty of GO lies in the fact that: it has simple rules but large and complex search

space. First, we need an unambiguous scoring or ranking scheme. In the game of GO, this is readily available known as the system of kyu and dan ranks. Second, computer games offer a low-risk environment for prototyping artificial learning. Third, online game engines are easy and cheap sources of large amount of data. Fourth, a game such as GO is complex in its strategies, where it relies on human ability to capture spatial patterns and connect information and patterns across the whole board, an important characteristic when we design artificial games or game-theoretic models on networks. The methodology is too generic that it can be applied to both real and artificial spatial game playing.

We structure the rest of the paper in three main sections. First, we present a tiny coverage of the literature related to this paper, taking into consideration that space constraints forced us to remove many references. Second, we present the methodology and analysis using real-human players. Third, we use this analysis to evolve artificial neural networks to reproduce similar behaviours. Finally, conclusions are drawn.

## Background Material

### Skills and Competency

The term *skills* refer to the learned capacities, whether general or domain-specific, that would be crucial/useful to perform a particular job (Bassellier, et al. 2001). Skills are the component competencies that collectively create the overall *competency*; i.e., the set of skills, knowledge, and qualities or "*behavior patterns*" which are needed to allow an agent to perform tasks/ functions with proficiency (Woodruffe, 1993).

Currently, evaluating the skills of strategic board-game players depends entirely on the degree to which the game's objectives are achieved (*i.e. final outcome*). Ranking systems – whether online or offline – are virtually the only objective method for automatically assessing the players' experience. However, subjective detailed assessments can frequently be obtained from experts, where different aspects of a player's skills may be evaluated. These types of studies have traditionally been answered through psychological and skill assessment tests (Groth-Marnat, 2009). We extend this approach to a computational environment to overcome the – sometimes – instability inherent in subjective assessment and reduce the resources required to do an assessment.

## Learning

Learning can be defined as: given a *task*, a *training-experience*, and a *performance-measure*, a system is assumed to be learning “if its performance at the task improves with experience” (Thrun & Pratt, 1998). A similar model can be found in (Osherson et al., 1986), where the learning process classically requires—beside a *learner*—an *item-to-be-learned*, an *environment* wherein the learner is shown the item-to-be-learned, and finally the *hypotheses* arising to the *learner*—given the *environment*—regarding the item-to-be-learned.

This characterizes the relationship between the learning process and *experience*; a concept greatly discussed—whether explicitly or implicitly—in topics related to the “*analysis of human performance*”, or in “*studies of learning and training*” (Farrington-Darby & Wilson, 2006). Experience does not necessary lead to more powerful thinking strategies and/or acquiring directly-perceivable cues—which the inexperienced are usually aware of—but rather to a more efficient employment of the strategies and cues based on the experience-base (Klein & Hoffman, 1993). Hence, experience can “*describe skills, knowledge, or abilities, in tasks, activities, jobs, sport and games*”, and it can “*refer to a process such as decision making or [...] to an output such as a decision*” (Farrington-Darby & Wilson, 2006).

Analysing online behaviour and interaction was also investigated in (François et al., 2007), where Self-Organizing Maps were used to classify online interaction between Autistic children and robots to detect the different play styles since “*interaction is decisive in the process of learning through play*.” Also, analysing and displaying users’ activity and interaction in an online system/community, whether in a competitive way (e.g. *ranking scores*) or an non-competitive way (e.g. *activity statuses*), was found to draw users attention and motivates users participation (Deiml-Seibt et al., 2009).

## Symbiotic Adaptive Neuro-Evolution

Symbiotic Adaptive Neuro-Evolution SANE (Moriarty & Miikkulainen, 1997) is an approach to neuro-evolution where two separate populations are evolved simultaneously instead of evolving a complete network. The two populations are neurons (*explicitly decomposing the search space by acting as local solutions*) and network blueprints (*exploring the best combinations of neurons*). Blueprints are considered a better alternative to building the networks out of randomly selected neurons. Usually, SANE develop three-tiered feed-forward NNs, evolving neurons for its single hidden layer. Each neuron defines a fixed number of weighted connections that are randomly assigned to both input- and output-layer nodes.

When applied to evolve Go player, each board intersection is represented by an input node for each player, and a single output node. It is illegal to activate both nodes representing an intersection. The first input node – per intersection – is activated iff the corresponding intersection is occupied by a white stone, and vice versa if the intersection is occupied by a black stone, the second input node is activated. An empty intersection is indicated by deactivating both input nodes. A sigmoid activation function is used for the output nodes. The next move is represented by the highest value (*corresponding to the best predicted move*). If the selected move is illegal, the move corresponding to the next highest activation is selected.

However, the network passes if all its output values are below a predefined threshold (*that is, 0.5 in our experimentation*).

The evolved NNs – the blueprints population – are evaluated by playing a game(s) of Go against the selected opponent, the fitness value is merely the final score(s). As for the neurons population, the fitness value for a neuron is the normalized summation of the fitness values of the blueprints in which it participated. Single point crossover is then applied on mates selected from the elite one third of the blueprints, and 25% of the neurons, creating two offspring that replace the worst individuals. Mutation is then applied conservatively to the neuron population, and more aggressively to the blueprints (*to maintain high diversity among the network*).

## The Game of Go

The game of Go is the oldest strategic board game in the world, and is also one of the most popular. Though the game is hard, the rules of the game are few and simple, easy to learn, and flexible enough to accommodate any board size as well as the standard 19×19 board. This two-player game, where players alternate placing stones on the intersections of the board, is theoretically in the same category as Chess, as both games are intellectually stimulating, requiring high-level strategic thinking, while also giving the chance for players to apply their tactical skills (Chikun, 1997). The differences between Go and other games (including Chess) in complexity measures is obvious in (Allis, 1994), with the complexities of Go far larger than that of any of the other perfect-information games. Unlike Chess, there are no Go programs that can challenge strong human players (Van der Werf, 2004), nor even moderate human players (Ernandes, 2005). Also, although 9×9 Go boards have a complexity between that of Chess and Othello (Bouzy & Cazenave, 2001), existing Go programs are still immature.

It is worth mentioning that the best known computational model for GO is Monte Carlo Simulation. No neural network or biologically inspired model exists as yet that can outperform Monte Carlo Simulation. As such, this study is a first step to potentially take a different approach towards building neuro-players.

## Methodology

The main idea of the proposed methodology is to exploit the possible computational building block(s) of human’s actions to assess their skills and competency. The methodology estimates human’s skill and competency levels through models trained on historical data of human with known skills and competency levels. The methodology has five main steps:

**Subject Identification and Selection:** The human subjects to be selected to form the training data need to have gone through multiple competency levels. In other words, this is a longitudinal study that commences with these subjects at a low competency level then moves up to higher ones during the data collection exercise. This is the most expensive step in the whole methodology, time-wise and dollar-wise, in the real world. The game of Go traditionally uses the ranking (rating) system of kyu and dan ranks. In this paper, players with ranks ranging from 30 to 20 kyu are collectively referred to as

*Beginners*, ranks from 19 to 10 kyu are *Casual* players, 9 to 1 kyu are *Intermediate* amateur players, and finally from 1 to 7 dan are *Advanced* amateur players. Due to some ambiguities in defining the *Professional* dan ranks in the game records, we have decided not to include those ranks in the analysis. We collected the games from *No Name Go Server (NNGS)* online game-archive (Adam, 2009). The cases – game records – were selected from the years' span 1995 up till 2005. Two datasets are selected separately, a Training Dataset '*trainDS*' which is used to train the proposed classifier, and a Testing Dataset '*testDS*' from which we will select a set of Go players to observe their behaviour.

We selected 381 games for training (127 for each category; *Casual*, *Intermediate*, and *Advanced*) based on some strict rules that the games should be complete, with a registered-name, and compatible players. We did not select '*Beginner*' cases because this category contains so much noise. The reason for this noise is that it contains all players who newly joined the server, not necessarily that they are beginners but they have not played enough on this server to establish a rank.

**Data Identification and Collection:** Every action performed by the human gets recorded. In the context of a game, actions are simply the board moves. In the case of a computer board game, the state of the board at each step of the game gets saved. The training data (*i.e. the data set that will be used to build the model*) needs to be labelled (*i.e. training subjects' skills and competency levels have been assessed by some other means*), preferably with no missing values, carrying a reasonable number of records for each subject over time and that spans the subject moving from one skill level to another, and of reasonable size. The richness of the data collected per subject, as our experiments demonstrated, means that we do not require a huge dataset to build the skill-assessment model.

Four hundred games were selected for the *testDS* with only 16 games found to be common between the two datasets. The 400 games were played by 246 distinct registered-names (*i.e. players*). We imposed a threshold of at least 10 games, yielding a final set of 15 players (Table 1) to be used for testing. In the first phase of the experiments, we will run our system using the *trainDS*.

**Model Knowledge Initialization:** Skill assessment requires a richer understanding of the domain, probably more than what is needed in a traditional data mining task. What is being recorded from the interface is mostly raw data that needs to be grouped, and possibly transformed to a different representation, before it can be used properly for skill assessment. These initial features form the basis for building the actual model.

We use spatial analysis of the board to establish what we call reasons for each move. Assume a move is played in a cell, the spatial analysis will see the different shapes that are newly formed by this move. These 48 reasons are then grouped into seven categories: a category of what it seems a bad move (*anti-suji*), a category for attack, a category for defence, a category for gaining an advantage, a category for deep planning, a category for end of game and an overall category of all reasons put together. These seven categories are named as: "*Not Recommended*", "*Considered an Attack*", "*Considered A Defence*", "*Explicit Gains*", "*Thoughtful*", "*End of the Game*" and "*All Reasons*" respectively.

Player ID	Number of Games Played	The Averaged Experience Range Covered by the Corresponding Player's Games
1	74	Upper-Beginner to Lower-Intermediate
2	38	Lower-Intermediate to Mid-Intermediate
3	32	Mid-Intermediate
4	46	Mid-Beginner to Mid-Casual
5	20	Lower-Intermediate
6	16	Mid-Casual to Lower-Intermediate
7	35	Mid-Casual to Upper-Casual
8	13	Mid-Casual to Upper-Casual
9	36	Upper-Intermediate
10	26	Lower-Intermediate to Mid-Intermediate
11	50	Lower-Advanced
12	11	Lower-Advanced
13	57	Upper-Intermediate to Lower-Advanced
14	10	Mid-Intermediate
15	34	Lower-Intermediate to Mid-Intermediate

Table 1: The final test dataset

It is obvious from the plain definition of each category that these categories can overlap. The Frequencies '*F*', Frequencies per Step '*FS*', and the Percentages '*P*', are applied as measurements for the aggregated subsets of the generated-reasons per game. Subsequently, and between each distinct pair of experiences, the Wilcoxon-test and a two-sample T-test were applied to statistically signify the ability of the calculated medians/means to differentiate between the corresponding distinct pair of experiences.

**Model Building:** The model can vary in its characteristics, ranging from simple statistics to complicated neural networks, decision trees, or classifier systems. The choice of the features in the previous step and the right model in this step are critical and can create all the differences between good or bad skill assessment models.

The *Median* and the *Median Absolute Deviation (MAD)* (Davies & Gather, 1993) were chosen as robust univariate measures in case the dataset is contaminated by outliers (*i.e. observations which appear to be inconsistent with the remainder of the dataset*) and thus subject to masking and/or swamping effects. Human players can be of a wide range of experiences, spanning from beginners to professionals. Given the set of experiences  $E = \{e_1, e_2, \dots, e_n\}$ , let  $D_e$  denote a subset of the dataset of all games  $D$  where the experience of both opponents is  $e$ . The median can be estimated as:

$$Median_{e,s,\varphi} = \left( \varphi_{[(|D_e|+1)/2]:|D_e|,R_s} + \varphi_{[|D_e|/2]+1:|D_e|,R_s} \right) / 2$$

where  $\varphi$  is the measurement function (*i.e. denoting F, FS, and P*),  $R_s$  is the *sth* reasons subset,  $|D_e|$  is the number of games in  $D_e$ , and  $\varphi_{1:|D_e|} \dots \varphi_{|D_e|:|D_e|}$  are the order statistics of

$\varphi_1 \dots \varphi_{|D_e|}$ . Accordingly, MAD can be estimated as:

$$MAD_{e,s,\varphi} = Median \left( \left| \varphi_{1:|D_e|,R_s} - Median_{e,s,\varphi} \right|, \dots, \left| \varphi_{|D_e|:|D_e|,R_s} - Median_{e,s,\varphi} \right| \right)$$

The medians of the different reasons subsets can model how the general strategy is decomposed into characterizing sub-

Measurements	Reasons' Subsets	Casual Games		Intermediate Games		Advanced Games

Table 2: The Medians and Median Absolute Deviations (MAD) of the different subsets, among diverse experiences

strategies, and demonstrates the variations in the strategies employed by human Go players of different experiences. To confirm the potential hypotheses suggested by the data, both a two-sample T-test and a two-sided Wilcoxon rank sum test are used. By permuting reasons subsets, estimated measurements, and pairs of different experiences, the T-test and Wilcoxon-test will respectively examine the null hypothesis that the data – *measurements per game* – have equal means/medians against the alternative that the means/medians are not equal.

The two-sample T-test tests a null hypothesis  $H_0$  that the two independent samples come from normal distributions with unknown variances and the same mean, against the alternative that the means are unequal. The test is two-tailed, and performed at a significance level  $\alpha = 0.05$ , i.e. the probability of mistakenly rejecting  $H_0$  (*Type I error*) is no more than 5%. Alternatively, the Wilcoxon-test tests a null hypothesis  $H_0$  that the two independent samples come from identical continuous distributions with the same median, against the alternative that the medians are unequal. The Wilcoxon-test is also performed at  $\alpha = 0.05$ .

In this study, a three-tier ensemble is used to predict the class label of a game of Go as *Casual*, *Intermediate*, or *Advanced*. The first-tier is based on Random Forests (RFs) (Breiman, 2001); ensembles of Classification Decision Trees (CDTs). In order to analyze the reasons, we are looking for a robust white-box model, which can handle data without requiring a lot of data preparation. These requirements suggest the use of CDTs. Each individual classifier (i.e., *RF*) is trained to classify a class and its complement; for example, a RF is trained to classify *Casual* games versus *Not-Casual* (i.e., *Intermediate* and *Advanced*) games, and so on. Thus, each RF outputs two probabilities 'Pr'; i.e. for the previous example, a probability that a given game is originating from the *Casual* class:  $\text{Pr}(C)$ , and a probability that the same given game is originating from the *Not-Casual* class:  $\text{Pr}(\neg C)$ .

In our experiments, a RF is an ensemble of – a maximum of – 1000 classification decision trees. A forest's attributes are

determined according to the *Error* and the *Size*; respectively, the minimum error (i.e., *misclassification probability for the out-of-bag observations*) recorded during the process of adding up trees while creating the forest and the ensemble size (i.e., *number of trees*) corresponding to that error value.

The second-tier creates an ensemble of RFs (i.e., a *Forest of Random Forests*) for each class then the joint probability distribution is calculated for two cases: that the instance belongs to the class and that the instance does not belong to the class. The third and final tier combines the results from the second-tier forests using a final gate-function to create for each observation (i.e., *game*) a single probability 'Pr<sub>final</sub>' per class. The final gate-function combines the probability that an instance is from one class and the probabilities that this instance does not belong to other classes.

Table 2 shows the medians and median absolute deviations among the 127 games per skill level and reasons' subsets. Table 2 shows a statistical difference between casual/intermediate and casual/advanced human Go players, yet it fails to differentiate between intermediate/advanced players. The medians tend to get higher with experience considering both *F* and *FS* as measurements; the only exceptions are when the medians of the advanced are lower than or almost equal to the corresponding intermediate in both subsets *Not Recommended* and *Explicit Gains*. Though this apparent correlation between the *F/FS* medians and the growing experience is expected to some extent, because more experienced players tend to play longer games, the two previously mentioned cases highlights the possibility that more experienced human players are less attracted by direct/instant gains and are more considerate when it comes to not recommended moves. This possibility is supported by medians reported for the measurement *P*, where the medians of both subsets almost decrease with growing experience.

Using *P* again, the medians of the subset *Considered A Defence* somewhat decreases with growing experience, suggesting that a more aggressive strategy is applied by well-

experienced human players, as opposed to a more defensive strategy by their less-experienced counterparts. The later suggestion is supported by the medians reported for the subset *Considered An Attack* which increase in correlation with growing experience in view of all of the three measurements. The medians reported for both subsets *Thoughtful* and *End of the Game* also increase in correlation with growing experience in view of all measurements.

Thus we can generally claim that, with rising experience, a human player's strategy evolves to a more thoughtful and aggressive strategy, a strategy that cares more about the final steps and eludes the not recommended moves, and last but not least, a strategy that is less lured by direct gains. This claim is statistically supported for human players who progress from casual to both intermediate and advanced experiences.

While using reasons greatly simplified and abstracted the typical knowledge used by humans, the use of aggregated sets of reasons additionally shortened the available reasons and allowed for the highest possible level of strategic abstraction. The three proposed measurements proved to be reasonable in quantifying the strategical aspects of the varying experiences.

Using the features generated per game, an initial preprocessing step is carried on by applying the Minimum Covariance Determinant (MCD) algorithm for outliers' detection. A MCD  $\alpha$ -value of 0.7 was selected, and all the games tagged as outliers were excluded from the *trainDS*. In this study, outliers are not considered noise or error, rather they are assumed to carry important information that accounts particularly for any unaccounted for parameters when selecting the dataset (for example, the length – number of moves per game). This step is followed by growing RFs that aim to use the previously calculated features to classify the games according to players' ranks. The preprocessing step showed that the measurement *FS* appears less affected by the potentially different or varying mechanism responsible for the outliers. Thus, *FS* is selected as the reliable measurement to monitor the players' competency and skills.

Using the uncontaminated *trainDS*, 30 RFs are trained to differentiate between each experience level and its complement. The 30 RFs trained – per experience, and using the *FS* – are combined to form the second-tier ensemble.

**Model Testing:** Once the model is built, it gets tested with subjects that were not included in the model building exercise. Upon successful testing, the model is ready for use.

Using the *testDS*, the games for each player are temporally ordered and then reasons were extracted to estimate the strategic reasoning behind the moves. *FS* is then applied – and combined according to the aggregated reasons' subsets – thus creating the final feature set for each game. The proposed classifier generates three final probabilities for each game:  $Pr_{final}(C)$ ,  $Pr_{final}(I)$ , and  $Pr_{final}(A)$  for Casual, Intermediate and Advanced respectively. Given the number of available experience-levels as  $N_{classes}$ , and the total number of games per a single player as  $N_{games}$ , three Competency Monitoring-Curves are plotted for each player; each representing the 'un-weighted' Cumulative Moving Average (CMA) for an experience-level, with a maximum window size of 50 games.

For space limitations, we will only show the results for one player with average predictive results to make the discussion more interesting. Figure 1 presents a 2-dimensional line graph

with two y-axes for the player. The left y-axis – 'Player's Experience Curves' – displays the value of the three Monitoring-Curves (i.e., generated probabilities), while the right y-axis – 'Ranks' Categories' – displays the Player's Rank according to the online NNGS archives. The Player's Rank curve is also a CMA of the actual rank-values. A label on the right y-axis represents the center of the respective rank category. The x-axis displays the game number, with imposed temporal frames for the corresponding dates (months/years).

The monitoring-curves in all of the resulting figures (including those not-shown) show a clear consistency between the experience level of a player and his/her probabilities' curves. That is, as the player 'assumably' gains more experience with time, the probabilities' curves reflect this learning activity by either declining or rising. Player#1 advances from an Upper-Beginner to a Lower-Intermediate experience over the course of the 74 games selected. Concurrently, the Casual-monitoring-curve of the mentioned player declines from 0.875 to around 0.5625, the Intermediate-curve also converges to around 0.5625 rising from 0.4375, and the Advanced curve is also rising from 0.3750 to a little bit higher than 0.5.

Figure 1: The Competency Probability-Curve for Player 1

Though, on strict classification bases, this player is classified as a Casual during the whole period (since the Casual probability curve is higher than both the Intermediate and Advanced), the clear trend in the curves assures that – with more games – the player is going to be correctly classified as Intermediate. Obviously, classifying a Beginner player as a Casual is reasonable in this context, since no Beginner cases were included in *trainDS*.

Here we reach the final stage of our results, in which we diagnose the skills learning-activity of human Go-players by temporally observing each of the strategies’ characteristics. A straight benefit of the figure is the distinctive opportunity to realize how the strategic reasoning of human Go-players is decomposed among the available strategies’ characteristics, and how those characteristics evolve temporally with experience. Figure 2 shows the normalized un-weighted CMA of the *FS* directly measured from the games. As a player progresses from being a Beginner to lower-Intermediate – through being a Casual – the categories ‘All Reasons’, ‘Considered an Attack’, ‘Considered a Defense’, and ‘Thoughtful’ seem – in general – to decline slightly with experience. The ‘Explicit Gains’ appears to be the only curve rising during the Beginner to lower-Intermediate progression. These findings are obvious in Figure 2. On the contrary, progressing from the Intermediate to Advanced shows precisely the opposite behavior. As players progress through

Our earlier findings seem to agree with only half of the later findings, that is, the changes occurring as a player progresses through the Intermediate rank and to being an Advanced. This apparent disagreement – where the categories ‘All Reasons’, ‘Considered an Attack’, ‘Considered a Defense’, and ‘Thoughtful’ seem to decline as a player advances from being a Beginner to a lower-Intermediate – can be attributed to two associated reasons. At first, in Table 2 no Beginner games matched the selection criteria, and therefore, the progression from Beginner to Casual was not investigated. That leads us to the second reason; the window size of 50 games employed in the CMA considers this ‘history’ of being a Beginner when the player has already advanced onto being a Casual, thus affecting the curves for an additional period.

## Strategically Aware Fitness Measurement

To accomplish this goal, SANE was used to evolve  $9 \times 9$  neuro-Go players using both the traditional exclusively score-dependent fitness function, and the proposed strategically-aware function. The networks are evolved against the GNU Go engine as an opponent. To compensate for the additional computational cost of estimating the strategies in the Go games, 50 blueprints are evolved instead of the 200 suggested by (Richards, et al. 1998). Due to the nature of the problem in which a network is evaluated by playing a game, and in spite of using elitism, the fitness values across generations fluctuate due to stochastic effect.

$$f_{Network} = \sum_{i=1}^{N_{Games}} \frac{\alpha Score_i + (1-\alpha)TP_i}{N_{Games}}$$

265

representing the *Network's* score in game  $i$ , while  $TP_i$  is the *Trained Probability* generated by the RF for the game  $i$ .

To investigate the effect of the added TP, the coefficient  $\alpha$  was varied, using four values;  $1.0$ ,  $0.8$ ,  $0.2$ , and  $0.0$ . The first  $\alpha$  value represent the traditional score-based fitness function, while  $\alpha$  set to  $0$  represents the case where the networks' evaluation is based entirely on the Trained Probability.

In General, the parameters in the experiments are based on those found effective in (Richards, et al. 1998), except for the number of blueprints which was reduced from  $200$  to  $50$ . A single run consists of  $500$  generations, and  $10$  different runs were evolved. The  $500$  generations are twice the number of generations required by SANE to evolve a network capable of defeating Wally on  $9 \times 9$  boards in (Richards, et al. 1998). Since Wally is a trivial engine when compared to GNU Go, GNU Go's level was set to  $1$  throughout the experiments instead of the default of  $10$ . However, GNU Go – even when playing at level  $1$  – is much more developed than Wally. Therefore, we do not expect to evolve a NN that is capable of defeating GNU Go, but a network that has developed enough strategies to be explored.

The games were scored using Chinese rules. The networks were always evolved to play White, thus never making the first move. The komi value – necessary to avoid a tie – was set to  $0.5$ , and no handicap stones were given to the networks. An upper bound of  $200$  moves per game was placed, to ensure that unreasonably long move-sequences that are probably suggested by the untrained networks are not pursued. This experimental setup cost up to a maximum of  $27$  days for a single run per an  $\alpha$  value using a Sun Constellation Cluster.

## Results and Discussion

In order to investigate the effect of the proposed fitness function, two different types analysis – to the neuro-evolution process – are to be shown and discussed. We start by showing and discussing the convergence among the varying  $\alpha$  values. Then a Tournament between selected players and GNU Go – set to different levels – is held.

Figure 3 shows the convergence of the  $50$  blueprints and  $4000$  neurons evolved using SANE for  $500$  generations. For each  $\alpha$  value, the average fitness – of  $10$  different runs – for the 1) best network, and the 2) entire population are plotted.

The convergence of the fitness values of all of the different combinations enters a relative plateau, starting from around generation number  $50$  for both  $\alpha$  values of  $0.2$  and  $0.8$ , and followed by generation number  $150$  for both  $\alpha$  values of  $0.0$  and  $1.0$ . The same is true for the convergence of the entire population, except for  $\alpha = 0.0$  where the population seems to continue evolving. Notably, the 'relative' difference between the best network and the population in terms of fitness values decreases with an increasing  $\alpha$ , except for  $\alpha = 0.8$  which shows the lowest difference. A possible explanation is that while depending more on the TP component rather than the score, the evolving networks increasingly fluctuate between the generations. However, setting to  $\alpha = 0.8$  shows a less varying fitness than  $\alpha = 1.0$ , even in other detailed figures that are not shown here due to page constraints.

The first step to investigate the playing capabilities evolved and whether it takes advantage of the engine's weaknesses is

by holding a tournament between selected representative players and GNU Go. As we mentioned before, SANE used a weaker player than GNU Go at level  $1$  as an opponent. The behavior of the evolved players when playing against GNU Go set to different levels will shed a light on the type of the strategies evolved. The tournament involves GNU Go at  $10$  different levels, starting from  $1$  (weakest) to  $10$  (default).

Figure 3: The Convergence of the Fitness Values

A simple and straightforward criteria is used to select a representative player for each of the varying  $\alpha$  values; the network achieving the overall best 'game score' across the  $10$  runs and the  $500$  generations. Figure 4 shows the best games' scores across the  $10$  runs, the best score for each  $\alpha$  is encircled. The maximum possible score using the Chinese rules – and a komi value of  $0.5$  – on a  $9 \times 9$  board is  $81.5$ .

Figure 4: Best Games' Scores across the 10 runs

The tournament consists of the four selected players versus GNU Go at  $10$  different levels. The players will be named *PlayerA*, *PlayerB*, *PlayerC*, and *PlayerD*; representing respectively the  $\alpha$  values of  $1.0$ ,  $0.8$ ,  $0.2$ , and  $0.0$ . For each pair – that is, a selected player versus a GNU Go at a single level –  $30$  different matches were played. The komi value is set to  $0.5$ , the games are scored using Chinese rules, and the GNU Go always starts the games.

Table 3 shows the percentage of Wins of the 4 selected players against GNU Go. Even though none of the players were able to defeat GNU Go at a level higher than the one they were evolved against, as  $\alpha$  decreases, the percentages of wins against GNU Go at level 1 increases until it reaches 20% of the games for *PlayerD*. This finding strongly suggests that the networks evolved using the proposed fitness function evolve different varying strategies to defeat the opponent. Even if those players were selected from premature generations; *PlayerC* was evolved in the seventh generation.

		Selected Players			
Details	<i>Alpha Value</i>	<i>A</i>	<i>B</i>	<i>C</i>	<i>D</i>
	<i>Corresponding Generation</i>	283	173	7	300
The Level of GNU Go	1	6.7%	10%	13.3%	20%
	2	0%	0%	0%	0%
	3	0%	0%	0%	0%
	.	.	.	.	.
	.	.	.	.	.
	10	0%	0%	0%	0%

Table 3: Selected Players' Details and Percentages of Wins

The main objective in a game of Go is to secure a territory. The capability of creating and defending a group of connected stones that remains alive – i.e., do not get captured – until the end of the game is fundamental to a go player. Therefore, the final scores of the games, even in cases of losing, are meaningful to our analysis. Players that can secure bigger territories than other players, and which will be reflected in the final score, are relatively more trained.

Figure 5 shows the average score of the selected players against GNU Go. Since GNU Go always plays as the black, and given the komi value of 0.5, the minimum possible score for the selected players is -80.5. All players report their best results when playing against level 1. For higher levels, Players C and D report the minimum possible score. However, *PlayerB* reports better average scores in most of the higher levels than *PlayerA*.

Figure 5: The Average Score against GNU Go

## Conclusions and Future Work

We provided a methodology for an automatic and objective assessment and monitoring of human-players' skills and competencies in the game of Go. The generality of the approach entails that the models can be used to assess artificial players as well, which we successfully demonstrated using an Artificial Neural Network. The findings are seen as advancement towards better understanding of human strategies to assess the skill levels of humans. For example, if player's skills are constant for a while, and if the objective is to improve the performance of that player, the artificial life environment or a game environment may switch to some training scenarios to improve the specific skills which have been stagnating. If the aim is to entertain the person, the game may alternate between an easier version and a harder version.

# Non-Template Molecules Designed For Open-Ended Evolution

Chris Gordon-Smith<sup>1</sup>

<sup>1</sup>SimSoup  
c.gordonsmith@gmail.com

## Abstract

Theories of the Origin of Life can be categorised as ‘template replication first’ and ‘metabolism first’. A key question for metabolism first theories is whether metabolic systems can support open-ended evolution; this is related to the number of possible persistent states of such a system. Earlier work<sup>1</sup> has demonstrated that artificial chemical systems can have memory; an essential requirement for inheritance. The current paper extends this, taking a ‘proof of concept’ approach to the question of the number of persistent states. It shows an artificial chemical network forming a ‘memory bank’ with many possible states. It also makes the link between chemical network structure and molecular structure, and provides a design for a set of artificial molecular species for the memory bank network. Preliminary simulation results from the SimSoup artificial chemistry simulator are included, confirming the operation of an initial set of ‘memory units’. The work supports the view that open-ended evolution can begin without requiring highly complex template molecules.

## Motivation, Approach, And Paper Overview

Metabolic theories of the Origin of Life propose that early organisms were metabolic systems that transmitted inherited information without the use of template replicating molecules such as DNA and RNA, and without the very complex mechanisms needed for their accurate replication<sup>2</sup>.

It is envisaged that the systems were individuals capable of growth and reproduction; in some theories they are thought of as protocells that could divide. Variations in the metabolisms of different individuals would have led to differences in fitness that would drive evolution.

For this to be workable, successful variations would have to be retained and passed on to offspring. In addition, for evolution to be effective it would need to be open-ended, with a large number of possible variations in metabolism.

The motivation for this paper is to investigate whether this is feasible. A ‘proof of concept’ approach is adopted in

<sup>1</sup>See Gordon-Smith (2005, 2007, 2009a,b) for earlier papers including SimSoup model details, and SimSoup (2011) for open source program code.

<sup>2</sup>Such mechanisms are prebiotically implausible, and so problematic for template replication first theories.

which an artificial chemical network and associated molecular structures are *designed* for open-ended evolution. If the structures identified are not too complex, then it is reasonable to suppose that molecules with similar capabilities and properties could have occurred in the prebiotic world.

## Conceptual Background

The SimSoup project takes inspiration from:-

- Metabolic theories including those of Aleksandr Oparin (Oparin, 1957), Stuart Kauffman (Kauffman, 1993), Freeman Dyson (Dyson, 1999), Chrisantha Fernando and Jonathan Rowe (Fernando and Rowe, 2007), and the Lipid World theory and GARD model of Doron Lancet's group (Segré et al., 1998, 2001a,b)
- Graham Cairns-Smith's clay crystal and genetic takeover theory (Cairns-Smith, 1982)
- Tibor Gánti's work on the principles of life and chemoton theory (Gánti, 2003)
- Network theory, particularly the work of Sanjay Jain and Sandeep Krishna (Jain and Krishna, 1998; Krishna, 2003)
- The Chemical Organisation Theory of Peter Dittrich and Pietro Speroni di Fenzio (Dittrich and di Fenzio, 2007)
- Günter Wächtershäuser's chemo-autotrophic Iron-Sulphur World (Wächtershäuser, 1990, 1997, 2006)
- Linus Pauling's chemical bond theory (Pauling, 1960).

## Memory In Chemical Networks

### A Network Oriented View Of Chemistry

This section presents a network oriented view of chemistry, and introduces terminology used in SimSoup.

**Network Components** The basic units of chemistry are particles and elementary reactions between these particles. The particles can be molecules or ions and are of different types (species). In an elementary reaction, one or more particles reacts directly to form products in a single reaction step and with a single transition state.

In SimSoup, a species of particle is called a *Molecule Type*, and an elementary reaction with particular Reactant(s) and Product(s) is called an *Interaction Type*. An instance of a Molecule Type is a *Molecule*, and an instance of an Interaction Type is an *Interaction*.

From a network point of view<sup>4</sup>, there are only three forms

<sup>4</sup>A network constructed from elements as shown in Figure 1 is not a graph in which the vertices represent Molecule Types and the edges represent Interaction Types. Constructions and Fissions each have three vertices connected by two edges, whereas each edge in a graph has only two vertices.

A chemical network can be represented by a *directed bipartite graph*. A bipartite graph has vertices that can be divided into two disjoint sets U and V such that every edge connects a vertex in U to one in V. In a directed bipartite graph, each edge has a direction.

Alternatively, a chemical network can be represented by a *directed hypergraph*; a hypergraph is a generalisation of a graph in which a 'hyperedge' can connect any number of vertices. In a directed hypergraph, hyperedges connect 'head' vertices to 'tail' vertices. The network elements of Figure 1 can be regarded as edges in a directed hypergraph.

of elementary reaction as follows (see Figure 1):-

- **Construction:** Two Reactant Molecules join to form a single Product Molecule
- **Transformation:** A single Reactant Molecule re-arranges to form a Product with the same atomic composition, but different structure
- **Fission:** A single Reactant Molecule splits to form two Product Molecules.

Figure 1: The three forms of Interaction Type. In Construction C1, Reactant Molecules of types A and B join to form a Product of type C. In Transformation T1, a Molecule of type D re-arranges to form a Molecule of type E. In Fission F1, a Molecule of type F splits into Molecules of types G and H.

**Compound Interactions** More complex reactions can take place as a result of Interaction Types combining in various sequences. Figure 2 shows a compound interaction with overall scheme  $A + B \rightarrow E + F$ .

Figure 2: A Compound Interaction

A Compound Interaction does not have a rate constant that determines the reaction rate according to the concentration(s) of the (non-intermediate) Reactant(s). In Figure 2, the reaction dynamics depend on the concentrations of C and D, as well as of A and B. If the Compound Interaction forms part of a larger network, C and D may be Reactants or Products for other Interaction Types, and so the reaction depends on factors other than the concentrations of A and B.

**Static And Dynamic Chemical Networks** A set of Molecule Types and Interaction Types (along with temperature and pressure dependent rate constants) define a *static network*. This is determined for all time by the laws of physics. A *dynamic network* is a set of actual Molecules and actual Interactions taking place between them at particular rates. As such, it is a possible process that can occur within the framework of a static network.

Figure 3: Catalysis Example

**Catalysis** The word ‘Catalyst’ does not denote a kind of Molecule. It denotes a *role* that a Molecule can play in a chemical process. In Figure 3, X plays the role of a catalyst; it is used by Construction C1, and released by Fission F1, so that overall it is neither consumed nor produced.

## Network Memory And Exploration

**A Two State Memory Unit** Figure 4 shows a simple (static) network for an artificial chemistry consisting of three elementary reactions C1, F1 and F2:

Figure 4: A two state chemical memory unit.

A is abundantly available ‘food’; initially no other Molecules are present. In the absence of X Molecules, Construction C1 cannot proceed and A remains the only Molecule Type present. If a single Molecule of X is introduced, a Molecule of I1 is produced (Construction C1). This then splits (Fission F1) to release an X Molecule and an I2 Molecule. The I2 Molecule then splits (Fission F2) to release another X Molecule plus a B Molecule. Overall, for each A Molecule consumed, one new X Molecule becomes available in addition to the B Molecule. As a result, the supply of X is maintained (even if there is some ‘leakage’).

The network is bistable; it has two states, one in which only A Molecules are present and no Interactions occur, and another in which Interactions proceed and X is maintained. The introduction of a single Molecule of X is ‘remembered’ because it triggers a switch to a new persistent state.

The network therefore constitutes a simple memory unit with an information capacity of 1 bit<sup>5</sup>.

<sup>5</sup>Under the current design for the memory unit, state changes of the unit are not reversible. However, such changes *can* be reversed at the ecosystem level. See the ‘Discussion’ section below.

## The Dynamic Network Explores The Static Network

Figure 5 shows a static network in which two of the memory units in Figure 4 are connected in series.

Figure 5: A two unit memory network with three states

If only A is available as ‘food’, there are three possible persistent states of the dynamic network: i) neither unit is active (only A is present), ii) only unit 1 is active, iii) both units are active.

In a more general situation where the static network is (effectively) infinite, we can consider a dynamic network to be ‘exploring’ the static network. A perturbation (such as the addition of a single X or Y molecule) can cause new parts of the network to become accessible.

## Network Structure For High Memory Capacity

The previous section described how simple two-state memory units can be combined to form a larger network with more stable states and so higher memory capacity.

This section presents a network that systematically combines a large number of memory units to form a network with a correspondingly large memory capacity.

## Memory Unit Sub-Network

Figure 6 shows a two state network that will form a memory unit within a larger ‘memory bank’ network<sup>6</sup>.

$P_{s,p-1}$  and  $D_{sp}$  are ‘food’. The Interaction Types in the network are as follows:

If a Molecule of  $M_{sp}$  is added to the food, then an Interaction of each of the four types can take place in sequence (C1, C2, F3, F4). The overall scheme for this sequence of Interactions is:

The sequence can only proceed if at least one Molecule of  $M_{sp}$  is present, but once the reaction has started it continues due to the excess production of  $M_{sp}$ .

There is nothing ‘special’ about the sequence C1, C2, F3, F4. If the Interactions are considered in different sequences

<sup>6</sup>Molecule Type name convention:  $M_{sp}$ ,  $P_{sp}$  and  $D_{sp}$  indicate a monomer, polymer and ‘closed dimer’ respectively. See the section covering molecular structure for further explanation.

Figure 6: A memory unit for the ‘memory bank’. Molecule Types are colour coded as follows: red - input to this unit, blue - output from this unit to the next unit, green - intermediate products. The blue and green Molecule Types together form an autocatalytic set. If the inputs are present, a Molecule of any member of the set can activate the network.

then it can be seen that a single Molecule of any one of  $P_{sp}$ ,  $P_{sp}D_{sp}$  or  $P_{sp}M_{sp}$  (in addition to the food) is also sufficient to activate the network.

In short  $M_{sp}$ ,  $P_{sp}$ ,  $P_{sp}D_{sp}$  and  $P_{sp}M_{sp}$  are an autocatalytic set that can be activated by any member of the set.

## A Memory Bank Network

Figure 7 shows a ‘memory bank’ of 25 units in five independent rows or *series*. Each unit has a label  $U_{sp}$ , where  $s$  indicates the series, and  $p$  indicates the *position* of the unit in its series. Each unit has the structure shown in Figure 6, with only the specific Molecule Types varying. The large circles on the left of the diagram represent a maintained food set.

Figure 7: A Memory Bank with 25 units.

In each series the food provides the input to the first unit, and the outputs of each unit provide the inputs to the next unit. Each unit in a series may be either active or inactive; shading indicates an active unit. The next unit in a series can only become active if its predecessor is active (the maintained food set is considered to be the predecessor of the first unit, and is always active). The labels of the form  $M_{sp}$  over the arrows represent Molecule Types that will, if introduced in very small quantities, activate unit  $U_{sp}$  provided its predecessor is active.

Overall, the diagram represents a static network in which each of the five series has 6 possible states (from no units active, to all five active), so that the network as a whole can have  $6^5 = 7776$  different states. A network with ten series of nine units would have  $10^{10}$  possible states.

## Molecular Structure For The Memory Units

In this section the link between network structure and molecular structure is made. A set of SimSoup Molecule Types that produce the memory bank of the previous section is described.

## Molecular Structure in SimSoup

The approach to modelling molecular structure has been described elsewhere (Gordon-Smith, 2009b). It is summarised here, and an extension introduced for the work discussed here is described.

Molecules are two dimensional rigid structures built from Atoms bonded together such that they occupy fixed positions on a square ‘Board’ (similar to a chess board). Each square contains at most one Atom. Bond angles are always  $90^\circ$  or  $180^\circ$ , and bond lengths are all equal. Atoms bond together in a way broadly consistent with valence bond theory.

Molecules can Join or Split to form Molecules of different types. Joining must respect the ‘one Atom per square’ rule. Splitting occurs by breaking the weakest set of bonds that hold the Molecule into a single unit.

Bond strengths are usually fixed according to the types of Atom at each end of a bond. The extension introduced for this work is that in some cases, a bond can be perturbed (weakened or strengthened) by the proximity of Atoms that do not themselves participate in the bond.

## Atom Types For The Memory Unit Molecules

The SimSoup Atom Types used for the Memory Unit Molecule Types are described below:

- **Assemblite:** Forms two bonds. Can be used to assemble the structural framework for a Molecule. Colour: black
- **Stoppite:** Forms one bond, and when present at a bonding site stops further growth of the Molecule at that site (much as Hydrogen does in an organic molecule). Colour: grey

- **Junction:** Forms three bonds. Can be used to provide a 3 way junction in a structure. Colour: **blue**
- **Loosium<sup>7</sup>:** Forms three bonds. Can provide a weak (loose) bonding site within a structure. Does not bond to Anti-Loosium. Colour: **spring green**
- **Anti-Loosium:** Forms three bonds. Can provide a weak (loose) bonding site within a structure. Does not bond to Loosium. Colour: **cyan**
- **Grabite:** Forms three bonds. Can provide a bonding site in one monomer for another monomer to 'grab' as part of building a polymer. Colour: **red**
- **Hookite:** Forms two bonds. Can provide a 'hook' that can attach to an atom of Grabite to form a bond as part of building a polymer. Colour: **green**
- **Perturbium:** Forms three bonds. Bonds can be weakened or strengthened by nearby Metal atoms. Colour: **magenta**
- **Metal:** Forms one bond. Can perturb nearby Perturbium/Perturbium bonds, even though not bonded to Perturbium. Colour: **orange**.

## Memory Unit Molecule Structures And Dimer Splitting

**Monomers, Polymers And Closed Dimers** This section describes the structures of Molecule Types that appear as Reactants for Constructions C1 and C2 in Figure 6.

Molecule Types of the form  $M_{sp}$  are *monomers*, those of the form  $P_{sp}$  and  $P_{s,p-1}$  are (short) *polymers*, and those of the form  $D_{sp}$  are *closed dimers*.

Figure 8 shows examples. Figure 8a shows monomer  $M_{01}$  and its structural units. The positions of the two recesses labelled  $S = 0$  and  $P = 1$  vary as the series  $s$  and position  $p$  indices vary. The recesses are called the *series recess* and the *position recess* respectively.

Along the top of each monomer are three small projections and a recess. The left hand *series projection* is directly above the series recess. The middle *position projection* is one place to the left of the position recess.

Figure 8b shows polymer  $P_{01}$ . The naming convention for polymers is such that  $P_{sp}$  represents a polymer of length  $p + 1$  whose end monomers are  $M_{s0}$  and  $M_{s,p}$ .

The positions of the recesses and projections on the top and bottom of the monomers ensure that two monomers can only join in a polymer if they are in the same series (same  $s$  index) and their position ( $p$ ) indices differ by 1.

The Half-Probes and Half-Acceptor on each monomer also have recesses/projections, and the positions of these are similarly dependent on the series and position indices.

<sup>7</sup>Only two of the bonds supported by Loosium and Anti-Loosium are used for the memory unit Molecules.

(a) Monomer  $M_{01}$  showing structural units

(b) Polymer  $P_{01}$

(c) Closed Dimer  $D_{01}$

(d) Polymer  $P_{03}$

Figure 8: Example monomer, closed dimer, and polymers. See the supplementary material for larger examples.

The structure of the monomers allows for both  $s$  and  $p$  to vary between 0 and 9. There are therefore 100 possible monomer types, and these can be used to construct 10 series of polymers, with polymers in each series being built from up to 10 monomers. Each series corresponds to a row in an enlarged version of the memory bank of Figure 7.

Figure 8c shows a closed dimer, formed by joining two monomers 'back to back'.

Finally, Figure 8d shows  $P_{03}$ , a polymer of length 4.

**Dimer Splitting Intermediates And The Splitting Mechanism** Figure 9 shows the structure of the Fission Reactants in Figure 6. Figure 9a shows Molecule Type  $P_{01}D_{01}$ . Figure 9b shows Molecule Type  $P_{01}M_{01}$ .

Dimer splitting is a key mechanism for the memory unit. It provides the means by which the autocatalytic set of Figure 6 maintains itself. Taking the example of Figure 9,

Figure 9: Dimer splitting intermediates

a Molecule of  $P_{01}D_{01}$  first splits (Fission F3) to release a Molecule of  $P_{01}M_{01}$  plus an  $M_{01}$  monomer, and then the  $P_{01}M_{01}$  Molecule splits (Fission F4) to release a  $P_{01}$  Molecule plus a second  $M_{01}$  monomer.

In short, the autocatalytic set maintains itself by splitting a ‘food’ dimer  $D_{sp}$  to produce a surplus of the monomer  $M_{sp}$ .

Dimer splitting involves a mechanism in which a polymer temporarily binds a dimer, and as result the Perturbium/Perturbium bond that holds the dimer together is weakened. The details of this can be explained by reference to Figure 10, which shows the central part of  $P_{01}D_{01}$ .

Figure 10: The central part of  $P_{01}D_{01}$ , showing the way in which the polymer ( $P_{01}$ ) part on the right ‘attacks’ and weakens the dimer ( $D_{01}$ ) part on the left at the bond between the two magenta Perturbium Atoms. The two parts of  $P_{01}D_{01}$  are held together temporarily by the weak bond between the two cyan Anti-Loosium Atoms.

The dimer and polymer parts are weakly bound at the Anti-Loosium/Anti-Loosium bond that joins the Locator of the  $M_{01}$  part of  $P_{01}$  to the bottom right of  $D_{01}$ . The memory mechanism relies on  $D_{sp}$  being split by  $P_{sp}$ , and not by any other polymer. ‘Incorrect’ splitting is ruled out because the two Half Probes on  $P_{sp}$  must be an exact match for the two Half-Acceptors on  $D_{01}$ .

The dimer weakening occurs because the two (orange)

Metal Atoms at the end of the two Half-Probes on the polymer are close to the two (magenta) Perturbium atoms on the dimer. This weakens the bond between them, and the dimer splits. The top ( $M_{01}$ ) part of the dimer falls away because it has no other bond either with the polymer or with the other ( $M_{01}$ ) part of the dimer. The other part of the dimer also spits from the polymer shortly afterwards, because the Anti-Loosium/Anti-Loosium bond holding the two together is weak, and so can only be temporary.

To summarise: A  $P_{sp}$  polymer binds temporarily to a  $D_{sp}$  dimer, and as a result the dimer is weakened. Both parts of the dimer separate from the polymer, which is then free to split another dimer. A dimer can only be split by the ‘correct’ polymer because the Probe and Acceptor formed by the Half-Probes and Half-Acceptors of the monomers involved must have compatible shapes.

## Results

Preliminary ‘proof of concept’ tests have been undertaken to investigate the workability of the memory bank described above. The tests used the SimSoup artificial chemistry simulator. Reactions take place in a well stirred Reactor. The rate constant  $k$  for Constructions is set to a constant value; those for Fissions are set to  $k = Ae^{-E_f/RT}$ , where  $E_f$  is the total energy of the bonds that have to be broken,  $T$  is temperature, and  $A$  and  $R$  are constants.

Results of two runs are presented. Both demonstrate memory; the first is typical of runs undertaken, the second illustrates an unusual ‘ringing’ phenomenon.

### Run 1

The scenario for Run 1 is as follows:

- Starting at time 1000, a constant supply of ‘food’ is provided to the Reactor. This consists of 400 Molecules of  $M_{00}$  every ten timesteps, plus 200 Molecules of each of  $D_{01}$ ,  $D_{02}$  and  $D_{03}$  every ten timesteps
- ‘Seed’ Molecules are added as follows: Five Molecules of  $M_{01}$  at time 10000, five Molecules of  $M_{02}$  at time 30000, five Molecules of  $M_{03}$  at time 50000
- At each timestep, every Molecule has a probability of 0.001 of being removed from the Reactor (‘leakage’)
- The size of Molecules was limited. This was necessary to enable the simulation to run within a reasonable time<sup>8</sup>

Figure 11 shows the numbers of the three polymers  $P_{01}$ ,  $P_{02}$  and  $P_{03}$  present in the Reactor at each timestep, along with the number of  $M_{00}$  Molecules<sup>9</sup>.

<sup>8</sup>The operation of SimSoup is such that whenever a new Molecule Type enters the Reactor as a result of two Molecules joining, all the possible ways the new molecular (‘board’) structure can interact with existing molecular structures must be calculated. This is computationally intensive.

<sup>9</sup> $M_{00}$  can be regarded as a polymer of length 1.

Figure 11: Plot showing the number of Molecules of  $M_{00}$ ,  $P_{01}$ ,  $P_{02}$  and  $P_{03}$  present in the Reactor during Run 1.

The addition of the ‘seed’ Molecules at times 10000, 30000 and 50000 in each case triggers a substantial change that persists over time. Prior to time 10000, there had been no Molecules of  $P_{01}$  present. Subsequent to the addition of the Molecules of  $M_{01}$  at that time, the number of  $P_{01}$  Molecules was stable at about 110 until time 30000.

Similar observations apply in regard to  $P_{02}$  and  $P_{03}$ . In each case, the seeding triggers a new persistent state in which the new Molecule Type is subsequently maintained.<sup>10</sup>

Figure 12: Manhattan Plot for Run 1. The black triangles indicate periods during which the Reactor composition (ie ‘mix’ of Molecule Types) varies little. The right hand edges of the triangles indicate sharp changes in composition.

Figure 12 is a ‘Manhattan Plot’ showing how the overall Reactor composition varied during the run. The construction of the Manhattan Plot has been described elsewhere (Gordon-Smith, 2007). The black triangles indicate periods during which there is little change in the composition (or ‘mix’) of Molecules in the Reactor.

The plot indicates that the pattern shown in Figure 11 in relation to a few key Molecule Types occurs more generally for the Reactor composition as a whole. There are periods

<sup>10</sup>The numbers of Molecules of existing types has a step change each time a new state is entered. This is to be expected since the overall dynamics of Interactions in the Reactor are changed. However, this does not lead to the disappearance of an existing type.

of roughly constant composition, and sharp changes corresponding to the addition of the ‘seed’ Molecules.

The number of Molecule Types present in the Reactor (not shown) was high; at the end of the run it was almost 500.

## Run 2

The scenario for Run 2 is similar to that for Run 1. There are differences in the timings at which Molecules are added.

Figure 13: Time series plot for Run 2, showing ‘ringing’.

Figure 13 is a time series plot for Run 2. ‘Seed’ Molecules are added at times 10000, 20000 and 30000. The system ‘remembers’ each seeding as for Run 1 in Figure 11. However, after the third seeding the system shows a variable oscillatory or ‘ringing’ behaviour before stabilising.

## Discussion

**Stability:** The stability of the active state of a memory unit derives from the positive feedback mechanism that it incorporates. The design strategy for Molecule Types to support feedback is as follows. Firstly, identify each memory unit with a short polymer  $P_{sp}$  that can be produced from  $P_{s,p-1}$  by the addition of an  $M_{sp}$  monomer, and which can catalytically split a closed dimer  $D_{sp}$  to produce more  $M_{sp}$  monomers. Then design the monomers to join only in ways that lead to production of the ‘correct’ polymers, and ensure that these polymers only split the ‘correct’ closed dimers.

Transition of a memory unit from the inactive to the active state can be triggered by addition of just a single monomer. A suppression mechanism could be added if necessary for stability, although this would add model complexity.

**Moderate Complexity Of Monomers:** The designed monomers are moderately complex, although far below the complexity of DNA and RNA and the molecules involved in their replication. There may be scope for simplification. It can also be envisaged that they could be products of some

systematic process that would result in co-ordination of the positions of the various projections and recesses.

**Bias In Direction Of State Changes:** Changes in state of a Memory Bank in an organism only take place in the direction of increasing  $p$ . However, this does not mean that evolutionary ‘mistakes’ cannot be reversed. If an organism is less fit as a result of a mutation then it will be less likely to persist in future generations. It may be possible to change the design of the molecules to remove the bias, but it does not rule out open-ended evolution at the ecosystem level.

**Integration With Larger Network:** Although the Memory Bank consists of a number of independent rows (or series), it can be envisaged to be integrated within a larger metabolic network that it influences.

## Conclusions And Prospects

### Conclusions

- An artificial chemical network and associated molecular structures designed to support up to  $10^{10}$  persistent states has been shown<sup>11</sup>. It is reasonable to suppose that this would be sufficient for open-ended evolution to begin
- The monomers are of only moderate complexity, supporting the view that molecules with similar capabilities and properties (though no doubt very different structure) were present in the prebiotic world
- The operation of a small set of memory units has been simulated, completing the first part of the proof of concept
- Supplementary material for this paper is available at <http://www.simsoup.info/Publications.html>

### Prospects

- It will be appropriate to make optimisations enabling a larger set of Memory Units to be tested
- The author would like to hear from anyone interested in translating the ideas described here to ‘real’ chemistry.

## Abstract

We present a “bestiary” of three digital organisms (self-replicating computer programs) that evolved in three different experimental environments in the Avida platform. The ancestral environments required the evolving organisms to use memory in different ways as they gathered information from the environment and made behavioral decisions. Each organism exhibited a behavior or algorithm of particular interest: 1) simple step-counting odometer; 2) clever low-level computation; and 3) pronounced modularity in both program structure and program functionality. We present descriptive in-depth analysis of the case study organisms, with a focus on the structure and operation of the evolved algorithms that produce the individuals’ fitness enhancing behaviors.

## Introduction

The multi-disciplinary nature of Artificial Life (Alife) makes for rich cross-fertilization between computer science and biology, with research that focuses on organizing principles of living systems (Bedau, 2007). In the broad context of evolving building blocks of simple intelligent behavior, we present experiments that address the interaction of memory, environment, and learning in an evolutionary context. Here, we recount the key points of work reported in Grabowski et al. (2010) and expand on that discussion. In the previous paper, we presented our experimental motivation and design, and gave a high-level view of the evolved behavior. In the current paper, we dissect the algorithms that lay beneath the evolved behaviors, exposing the low-level mechanisms that produce the fitness enhancing behaviors. We produced our analyses through instruction-by-instruction examination of execution traces of the evolved digital organisms.

An important aim of our approach is to inform inquiry in both computer science and biology. With that aim in mind, we selected three highly successful digital organisms that evolved in three different experimental environments. Each of the case study organisms has a salient feature or behavior that seems critical for the evolved solution to work. The first organism evolved a simple odometer that it uses to count its steps, turning immediately before it would have

otherwise entered an environmental hazard. The second organism evolved a computational strategy that uses low-level bit operations to ensure correct behavioral responses to cues from the environment. This computational tactic is of special interest because it produces high-level behavior from low-level operations, and it also exemplifies a foundational principle of biology and psychology, that evolution tends to produce parsimonious solutions to behavioral problems (“Morgan’s Canon,” Morgan (1894)). The third organism evolved distinct functional and structural modularity; the role of modularity is a topic of great interest in a number of contexts. These digital organisms were products of an open-ended evolution system, and the system did not explicitly select for any of the solutions. We are exploring the range of unexpected solutions that can come out of such a system. The diversity of the evolved solutions is broad, even though we are dissecting only a handful of examples.

## Methods

### Avida: Overview

Digital evolution (Adami et al., 2000) is a type of evolutionary computation that places a population of self-replicating computer programs (digital organisms) in a computational environment, where the population evolves as the organisms replicate, mutate and compete for environmental resources. Digital evolution is a useful tool for understanding evolutionary processes in biology and for leveraging evolution to find solutions to computing and engineering problems. Avida (Lenski et al., 2003; Ofria et al., 2009) is a widely used software platform for digital evolution. Avida is an instance of evolution in its own right (Pennock, 2007), and provides a host of tools for experimental studies. In this section, we provide a brief summary of how Avida functions. For more detailed information, see Ofria et al. (2009).

The Avida world is a discrete two-dimensional grid of cells that holds the population of digital organisms. At most one organism (Avidian) may occupy a grid cell. The genome of an Avidian is a circular list of program instructions that resemble assembly language, that runs in a virtual central processing unit (CPU). The organism’s CPU contains three

registers (AX, BX, and CX), two stacks, and several heads (FLOW, used as a target for jumps; IP, an instruction pointer that denotes the next command to be executed; READ, for reading an instruction; WRITE, for writing an instruction). Execution of the instructions in the organism's genome act on the elements of the virtual CPU, incurring a cost measured in virtual machine cycles. An Avidian accomplishes all functions by executing the instructions in its genome, such as movement, gathering information from its environment, or replicating. The basic Avida instruction set is Turing-complete (Ofria et al., 2002), and is easily extended by adding new instructions to the system.

An Avidian replicates by copying its genome into a new block of memory. Mutations in Avida occur through errors in this copying process that produce differences between the genomes of parent and offspring. These differences may take the form of inserting or deleting an instruction, or changing one instruction to another, and occur at random with a user-defined probability. The Avida instruction set has the property of remaining syntactically correct in the presence of mutations, so a mutated genome will continue to execute, even if it performs no useful functions (Ofria et al., 2002).

Newly-produced offspring are placed in a randomly selected grid cell, overwriting any organism that was occupying the cell. This process gives a fitness enhancing advantage to an organism that can replicate faster than others in the population; organisms compete for the limited resource of grid space, and individuals that replicate sooner than others will have a higher proportion of descendants in future populations. Avidians may replicate sooner if they speed up their execution by accumulating metabolic rate bonuses as they evolve to perform user-specified tasks. Fitness in Avida is measured as the organism's metabolic rate divided by the number of cycles the organism requires to replicate.

## Experiment Design

We placed each Avidian in an environment containing a path that it could follow to collect food and increase its metabolic rate. Our environments were inspired by maze-learning experiments with honey bees (Zhang et al., 2000). Organisms had to sense the cues that formed the path and react appropriately to them. In some cases, advantageous behavior involved the ability to store experience for later decision-making.

For these experiments, we added sensing and movement instructions to the basic Avida instruction set. The *sg-move* instruction allows an organism to move one cell in the direction of its current orientation (its facing). In this study, each digital organism had its own virtual grid, so organisms did not interact during movement. Two instructions accomplished orientation changes, *sg-rotate-right* for turning 45° to the right and *sg-rotate-left*, for turning 45° to the left.

We added a sensing instruction, *sg-sense*, that allowed the

Avidian to get sensory information from its environment. When an Avidian executes the sensing instruction, the instruction places a predefined value in the executing Avidian's BX register, according to which cue is present in the grid cell at the organism's current location. These values are analogous to sensory input that the organism obtains from the environment, and are not directly used in calculations. The operation of this *sg-sense* instruction is important to the analyses of the evolved programs. The virtual grids for these experiments had a sensory cue in each cell of the grid. The environments contained some combination of the following cues (Grabowski et al., 2010):

1. **Nutrient:** A cue that indicates a cell is on the path, and provides "food" (*i.e.*, energy that adds to the organism's metabolic bonus). The nutrient cue has a sense value of 0 from the *sg-sense* instruction.
2. **Directional cue:** A cue indicating that a 45° turn to either the right or left is needed to remain on the path; the cell also contains nutrient. Right turns and left turns have different sense values from *sg-sense*, 2 for right and 4 for left.
3. **General turn cue:** A cue that indicates a turn but does not specify the direction, and contains nutrient. The return value for the general turn cue is 1.
4. **Empty:** A cue that indicates a cell that is not on the path. Movement into empty cells depletes energy gained by movement into cells that are on the path. The *sg-sense* instruction returns a sense value of -1 for empty cells.

We added two new comparison instructions to the Avida instruction set, *if-greater-than-X* (*if-grt-X*) and *if-equal-to-X* (*if-equ-X*), that supplemented existing comparison instructions. These instructions allow an organism to compare the value in its BX register to a predefined value. A *no-op* (NOP) label immediately following the comparison instruction determines the value to use in the comparison. We added the new comparison instructions because an Avida organism has to combine several different arithmetic instructions in order to compare a register value to any specific value. The new *if-equ-X* and *if-grt-X* instructions provided a shortcut and simplified comparisons for the Avidians, and also contributed to evolved genomes that were simpler to analyze. The details of these new instructions did not adversely affect the adequacy of our model, since our focus in the experiments was on memory; the mechanisms of constructing comparisons are not relevant to our questions of interest.

We constructed several environment types using the cues described above. The three organisms that we present in this paper evolved in three different environments.

- **Environment 1 and Environment 2: Evolving reflexes.** The first two environments contain paths with directional

(right and/or left), nutrient, and empty cues. Paths in Environment 1 contained only one type of directional cue (right or left) in each path instance; they are “single-direction turn” environments (see Figure 1). Environment 2 paths contained both right and left turns in the same path, and so are “dual-turn” environments (see Figure 2a). With both of these environment types, we expected the organisms to evolve a reflexive reaction to the path cues that they sensed, since the sensory information did not have to be retained for decision-making in the individual’s future.

- **Environment 3: Evolving volatile memory.** This environment type uses all four sensory cue types. The specific directional cue (right or left) is encountered when the turn is the first turn on the path or when the turn direction changes (*e.g.*, the organism has done one or more right turns and now needs to turn left). The general turn cue is encountered when the turn direction is to remain the same as the previous turn (*e.g.*, the organism executed a left turn at the previous turning and the current turn is also to the left) (see Figure 2b). This arrangement requires the organisms to evolve mechanisms for storing, using, and updating information about their experience on the path they are traversing, equating to a simple form of memory.

Organisms were presented with one of several different paths of the particular environment type (four different paths for Environments 1 and 3, and five different paths for Environment 2), chosen at random when the organism was born. Each individual experienced only one specific path in its lifetime, but all of the environments were experienced by multiple organisms during the course of evolution. In all experiments, organisms could raise their metabolic rate bonus through a path traversal task. The details of the task are presented in Grabowski et al. (2010). We ran 50 experimental replicates for each environment type, seeding each experiment with an organism with only the ability to replicate. All other functions had to evolve, using instructions entering the organism’s genome through mutations. We used the default Avida mutation rates for all our experiments, a 0.085 genomic mutation rate for a length-100 organism (a 0.0075 copy-mutation probability per copied instruction, and insertion and deletion mutation probabilities of 0.05 per divide) (Ofria et al., 2009). Experiments ran for a median of approximately 33,000 generations (250,000 Avida updates). Our populations had a maximum of 3600 individuals.

## Results and Discussion

### Environment 1: Evolved Odometry

For Environment 1 (single-direction turn paths), we deliberately constructed simple paths with two regularities: each individual environment contained only right turns or only left turns, and the path progressed continuously outward from the starting position, giving the paths a spiral shape. There

was also one unintentional regularity: the ancestral right-turn paths were the same except for the organism’s starting position and the resulting distance to the first turn. The left-turn paths had more differences in the numbers of steps between turns. One population from this environment evolved a step-counting organism. This result is particularly exciting, since some animals use a mechanism analogous to step counting to determine the distance they have traveled on excursions away from their nests (Wittlinger et al., 2006). While odometry is considered a straightforward problem in robotics, it is by no means clear how it works in most animals, how it participates in higher-level processes such as path integration, and how it first evolved. Our approach may afford a way of exploring these problems.

Figure 1 shows trajectories of the Environment 1 example organism (Org:StepCount) moving on a right-turn-only path (Figure 1a) and on a left-turn-only path (Figure 1b). Org:StepCount’s evolved strategy performed well in both turn environments. Interestingly, Org:StepCount backtracked on the right-turn grid, *i.e.*, it turned around and retraced its steps on the path. This behavior did not reduce Org:StepCount’s metabolic rate; the task quality calculation rewarded movement into unique path cells but did not penalize an organism for multiple movements into a path cell (Grabowski et al., 2010). Org:StepCount was able to navigate the entire right-turn path without entering any empty cells and also successfully followed the left-turn-only path, stopping after it encountered a single empty cell.

We analyzed an execution trace of Org:StepCount while it traversed each of these two paths, to uncover how its algorithm produces the observed behavior. Most—but not all—of the movement and replication code of Org:StepCount’s program is organized into two sections. Some instructions for this behavior (*i.e.*, movement and replication) are scattered in other locations in the genome, so Org:StepCount is not completely modular. A distinctly modular organism evolved in Environment 3, discussed later. One of the code sections (“Section 1A”) handles moving on a right-turn path, and the second (“Section 1B”) focuses on left-turn paths. Section 1B also contains a nested copy loop that is used for replication. Both of these code sections execute, whether the organism is on a right-turn or left-turn path, but the resulting behavior differs according to the path type (*i.e.*, right or left). Section 1A is essentially a counting routine. When Org:StepCount is traversing a right-turn path, Section 1A counts its steps; for left-turn paths, Section 1A counts the number of 45° turns the organism executes. When on a left-turn path, Org:StepCount uses Section 1B to travel to the end of the path and then replicate. When Org:StepCount is on a right-turn path, Section 1B allows the organism to avoid stepping off the end of the path by retracing some of its steps, at the same time finishing its replication process.

The following is a pseudocode description of the functionality of Section 1A:

(a) Right Turn Path

(b) Left Turn Path

Figure 1: Trajectories of Org:StepCount on ancestral paths.

```
DO
  rotate right
  IF (CX > 0) copy
  copy
  CX <- sense
  IF (CX equal nutrient) rotate left
  ELSE IF (CX equal right turn)
    CX <- 128
    move
    BX <- BX + 1
  WHILE (BX not equal CX)
```

Org:StepCount's current environment (*i.e.*, left- or right-turn) determines how this code executes. When traversing a right-turn path, Org:StepCount uses this loop to count its steps to the end of the path. Setting the CX register to the value of 128 (by reading the current position of the Instruction Pointer (IP)) and incrementing the value in the BX register (which begins at a value of 0 at the first loop iteration) with every loop iteration sets up the exit condition for the loop: after Org:StepCount has taken 127 steps in the loop, the last increment of the BX register causes execution to exit the loop. When executing this loop on a left-turn path, the organism remains in the same spot and executes the loop four times, performing a one-eighth turn in each iteration. When the value of the BX counter reaches 4, Org:StepCount exits the loop, and is now facing in the “wrong” direction (*i.e.*, facing back the way it has already come). The section

of code immediately following this section includes another set of four one-eighth turns, so Org:StepCount regains the facing it had upon entering Section 1A.

Section 1B operates as follows:

```
DO
  move
  BX <- sense
  IF (BX not equal nutrient)
    rotate left
  IF (BX equal empty)
    WHILE (not end label) copy
  ELSE IF (not end label) copy
  IF (end label) divide
  WHILE (BX not equal empty) AND
    (not end label)
```

When this algorithm is executed on a left-turn-only path, Org:StepCount moves along the path, eventually moving one step off the end of the path into an empty cell. At that point, Org:StepCount “stands still,” and executes a tight copy loop to complete copying its genome to its offspring, at which time it divides. On a right-turn path, however, Org:StepCount never enters the tight copy loop; instead, it copies just one instruction for each iteration of Section 1B, while it retraces its steps along the path. This strategy produces the backtracking in the trajectory plot of Figure 1a. The organism retraces the path moving back toward its initial location, stopping part of the way through the path (red

octagonal symbol). The number of instructions needed to produce an offspring remain similar on right- and left- turn paths (1779 instructions for the right-turn path shown in Figure 1a and 1780 instructions for the left-turn path shown in Figure 1b) since an extra instruction is copied with every iteration of Section 1A when Org:StepCount is moving on a right-turn path. Table 1 lists the Avida instructions for the two code sections described above.

## Environment 2: Economical Code and Clever Math

Environment 2, the dual-turn environment, presents evolution with a slightly more complex version of the problem encountered in Environment 1, since evolution must always contend with both turn directions in every path. The evolved algorithm of the example organism from this environment (Org:BitOperator) is interesting because it evolved some remarkably clever math that helped it succeed in its environment, using simple, low-level computations to produce complex, high-level behavior.

Org:BitOperator successfully negotiated both ancestral paths and novel paths. Figure 2a shows Org:BitOperator's trajectory on a novel path. The dimensions of the grid containing the path are different from the dimensions of the grids in the ancestral environments: the novel path shown has dimensions of  $20 \times 20$ , as opposed to the  $25 \times 25$  grids that were experienced during evolution. Since all environment grids are toroidal, the grid dimensions should make no difference to organisms, and organisms never have access to any global information. However, we included tests like these to provide additional evidence that the evolved algorithms do not work by finding and exploiting geometrical information, such as grid size, but instead function through gathering and using information from the environment.

Org:BitOperator executes most of its movement with a

concentrated movement loop. At a high level, the structure of the code is *move-sense-decide*. The decision concerns whether or not to turn, and if a turn is to be made, which direction to turn. Within the loop, conditional statements guard the turn directions to provide the correct execution flow for each environmental cue. In pseudocode, this movement loop functions as follows:

```
DO
  IF (BX > 1) rotate left
  copy
  move
  BX <- sense
  BX <- right-shift(BX)           #Line 1
  IF (BX equal 1) rotate right #Line 2
  ELSE IF (BX < CX)               #Line 3
    IF (BX > 0) CONTINUE          #Line 4
  WHILE (BX > 0)
```

Org:BitOperator has a simple, but clever, mechanism for using the default behavior of the comparison instructions to select the correct action, based on the current sense information. Org:BitOperator manipulates the current sensed cue value so that the values match the comparisons as needed. The key detail of this loop's execution is how the right-shift operation (Line 1) prepares the sensed cue value for use with the unmodified comparison statements. Stepping through the algorithm, starting from the `BX<-sense` line, the current cell cue is sensed, and the value placed in BX. That value is then right-shifted, dividing most sense values by 2. Recall the return values from the *sg-sense* instruction. If the sensed cue is nutrient (return value = 0), BX is still 0; if the cue is right-turn (return value = 2), BX is now 1; if the cue is left-turn (return value = 4), BX is now 2; if the cue is empty (return = -1), BX is still -1 (since the operation is an arithmetic right-shift, the sign bit is preserved in the shift). This low-level manipulation of the sense value permits the algorithm to use the default behavior of the comparison instructions, thus avoiding the need for NOP modification of the instructions. This characteristic provides more robust performance for Org:BitOperator, since the comparison needs only one instruction to complete its action, not two. The first comparison (Line 2) is true when the last sensed cue is right-turn, so the right turn is executed. The next comparison (Line 3) is false for all cues except empty, so execution returns to the top of the loop as long as the organism encounters non-empty cells. Sensing an empty cell triggers loop exit.

This solution is simple and economical, accomplishing the job with few extraneous instructions. Org:BitOperator has evolved an equally frugal copy loop near the end of its genome. The copy loop performs the bulk of Org:BitOperator's replication, and begins execution only after the movement loop has terminated. Table 2 gives the Avida code for Org:BitOperator's movement loop. Not only is the elegance of these evolved solutions to be admired from

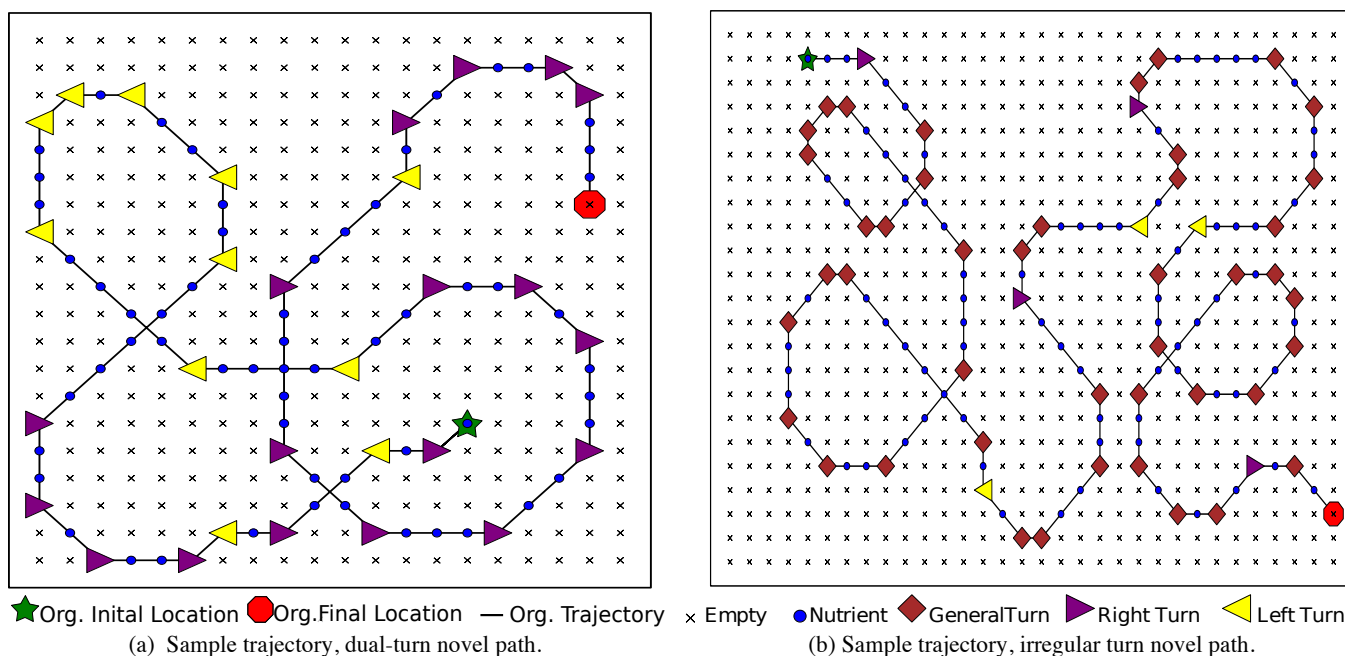

Figure 2: Trajectory of the two example evolved organisms from Environments 2 and 3. Figure 2a shows the example organism, Org:BitOperator, from Environment 2 (dual-turn paths) traveling on a novel path. The grid containing the path has different dimensions ( $20 \times 20$ ) from those of the ancestral paths ( $25 \times 25$ ). Figure 2b shows the example organism, Org:Modular, from Environment 3 (irregular paths) traversing a novel path. This path grid also has dimensions ( $23 \times 32$ ) that differ from those of the ancestral environments ( $25 \times 25$ ).

a computational perspective, they also provide evidence of “Morgan’s Canon,” a parsimony principle that has guided a century of research in animal and human psychology (Morgan, 1894). By this principle, one should prefer hypotheses that invoke simpler rather than more complex mechanisms of information processing. Our results suggest that digital evolution could lead to empirical study of this principle.

### Environment 3: Evolving Modularity

Environment 3 was the most complex environment in our study. To enhance fitness in this environment, organisms needed to make decisions based on their life experience, and update their memory of that experience at irregular intervals. The case study organism from this environment (Org:Modular, shown in Figure 2b traversing a novel path) evolved an algorithm with functional and structural modularity that provides appropriate behavioral responses to environmental conditions.

The execution of Org:Modular’s genome is fairly complex, with a high degree of flexibility to handle conditions in its environment. In general, Org:Modular moves its execution to different parts of its genome depending on the sensed cue from the environment. Org:Modular has two loops for its path-following, one loop that navigates left-turn path segments, “Module 3A,” and the other loop for traveling on right-turn path sections, “Module 3B.” Org:Modular has well-defined functional and structural modularity in its genome for handling right-turn and left-turn path sections. Such refined modularity was not observed in other organisms that we analyzed. Module 3A appears first in Org:Modular’s genome, before Module 3B. Module 3A can perform an arbitrary number of forward steps and consecutive left turns. This behavior in Module 3A is produced by a nested loop that results in straight-ahead movement on

the path; iterations of this smaller loop continue until a non-zero cue is sensed. The smaller loop terminates when a left-turn or general turn is sensed, but execution remains within Module 3A. Sensing a right-turn or empty cue will exit both the smaller loop and Module 3A. Module 3B enables Org:Modular to negotiate right-turn path sections, accommodating any number of repeated right turns and forward steps. Execution exits Module 3B upon sensing a left turn cue, and jumps to the beginning of the organism's genome, thereby arriving again at Module 3A. Execution of Module 3B terminates if an empty cell is sensed, continuing with the instructions following the module. Org:Modular also has a modular copy loop near the end of its genome that manages the majority of the copying for the organism's replication.

Module 3A, for navigating on left-turn path sections, functions as follows:

```
DO
  DO
    move
    BX <- sense
    IF (BX < CX)
      swap (BX, CX)
    BX <- BX - 1      # Line 1
    WHILE (BX < CX)   # Line 2
      rotate left
  WHILE (BX equal turn) OR (BX < CX)
```

The decrement of the value in BX following the sense instruction (Line 1) manipulates the value in the BX register such that execution remains in the nested loop as long as the organism is sensing nutrient cues (meaning that Org:Modular is moving straight on the path), but will exit the nested loop when any other cue is sensed. Whenever this module is executing, the value in CX is 0 at the top of the loop. Executing `BX <- BX-1` with the nutrient return value (0) places a value of -1 in BX, so execution does not exit the nested loop (Line 2). Decrementing the general turn cue return value (1) places a value of 0 in BX, causing execution to exit the nested loop and do the left turn. When the right-turn return value (2) is decremented, the value in BX becomes 1, and the nested loop is exited. Execution then exits Module 3A, after executing the left turn. The swap of values in BX and CX is executed only if an empty cell is sensed. The swap puts 0 in BX, and -1 in CX, so the nested loop is exited, and execution leaves Module 3A after the left turn, since BX is equal to CX after BX is decremented.

A pseudocode description of the functionality of Module 3B, for moving through right-turn path segments, is:

```
DO
  rotate right
  IF (BX < CX) BX <- sense
  move
  BX <- sense
  IF (BX equal turn) CONTINUE # Line 1
```

```
ELSE IF (BX equal left turn)
  jump IP to 0
  BX <- BX + 1
  rotate left
WHILE (BX not equal CX)
```

There is a section of instructions between the modules that has no move instructions, but has a single right-turn instruction that negates the last left turn performed before exiting Module 3A. An additional right-turn instruction executes before Module 3B entry, ensuring proper orientation for turning right, since Module 3B contains both right- and left-turn instructions that always execute. Correct orientation is maintained by selectively executing the left turn at the end of the module. When a general turn cue is sensed, execution in Module 3B skips the left turn (since `BX=1`), and returns directly to the top of the loop. When a nutrient is sensed, `BX=0`, so the increment of BX and the left turn are executed. When Org:Modular senses a left-turn cue, execution jumps out of Module 3B, returning to the beginning of the genome. As in Module 3A, the value in CX is 0 during execution of Module 3B. If an empty cell is sensed, incrementing the value places a value of 0 in BX, and execution exits the module. Once Org:Modular moves into an empty cell, execution moves to the copy loop, and Org:Modular completes its replication. Table 3 lists the Avida code for Org:Modular's path-following modules.

Two features of Org:Modular are particularly interesting. The first is the organization of the genome. The sections of the genome that do the bulk of the relevant behavior for Org:Modular—the two movement modules and the copy module—are functionally and spatially modular. For all three of these modules, very little happens within them apart from the main function of the module. The modules are also spatially modular, *i.e.*, located in different areas of the genome. Example organisms from the preceding experiments also demonstrate some structural modularity, but their functional modularity is less well-defined. The parallel with the structural and functional modularity seen in the neural control of animal behavior is striking (Bullmore and Sporns, 2009). The second feature of special interest is the flexibility of execution flow between code modules. The execution flow enables Org:Modular to cleverly handle all the contingencies of the environment. For example, even though Module 3A (left-turn module) is encountered first in the sequential execution of the genome, if a right turn is encountered first, the execution flow moves easily through Module 3A into Module 3B (right-turn module). The algorithm evolved to deftly maneuver along the paths, using the information of the cues from the environment to alter its execution.

We presented a “bestiary” of digital organisms, case studies of three evolved organisms that show the range of surprising solutions that can arise in open-ended evolving systems. Each example organism had a striking characteristic that highlights issues of interest in both computer sci-

ence and biology. Although it is premature to make broad generalizations based on our results, we can conclude that the Avidians evolved solutions that were well tailored to the task, neither more nor less complex than needed. The lesson of our results is that an evolutionary approach to higher levels of intelligence will require careful attention to both the computational resources available to the evolving system and to the complexity of the tasks presented by the environment.

The work that we report in this paper laid the foundation for several ongoing research projects. We are continuing our study of evolving navigation, including simple landmark navigation and vector navigation. The experiments discussed in this paper provide an excellent arena for investigating issues relating to historical contingency in evolution: how accidental changes to the genetics of a population shape the path of future evolution. Steps in evolution are thus dependent on prior history (Blount et al., 2008). We are exploring what factors determined what strategy evolved in our experiments.

Our results underscore how results from Artificial Life experiments can provide insight for different fields of study. The strategies shown by these case study organisms highlight the power of evolution to find surprising and clever solutions to problems. These solutions may guide the development of intelligent artificial agents, and also provide insights into the fundamental principles governing the early evolution of intelligent behavior in biological systems.

## Acknowledgments

## Abstract

To study the evolutionary process and the emergence of species, we have conceived an individual-based evolving predator-prey ecosystem simulation presented in (Gras, 2009). One major and unique contribution of this simulation is that it combines a behavioral, an evolutionary and a speciation mechanism. This is the only simulation modeling the fact that individual behaviors affect evolution and speciation. We have already obtained some very interesting and promising results from our simulation on species abundance distribution, study of chaotic patterns or population spatial distribution.

## Introduction

Since the last decade, the individual-based modeling approach became more common as machine capable of running time-consuming simulations appeared (DeAngelis, 2005). However, few attempts have been made to simulate a complete and complex ecosystem. The first one is Echo (Hraber, 1997), which includes an evolutionary mechanism. However, the organisms are very simple, and have no behavior model. Another system studying long term evolution is Avida (Lenski, 1999). It has nevertheless limitations such as: the individuals do not move, are quite limited in number, and there is a fix fitness function which means that the system is mostly an optimization process.

Other models, such as PolyWorld (Yaeger, 1992), Bubbleworld.Evo (schmickl, 2006) or Framsticks (Comosinski, 2000), have been proposed including more complex agents and behavioral models. They use Artificial Neural Networks or system of learned rules to evolve the agent's behavioral model during their life and by an evolutionary process. However, these approaches are highly computational expensive and only allows small population (few hundred) of agents. They are therefore more dedicated to investigate evolution of learning capacities than high scale mechanisms involving populations and species dynamics. To investigate several open theoretic ecological questions we have designed, Ecosim<sup>1</sup> (Gras, 2009), a large scale simulation platform. Our general purpose is to study how individuals and local events can affect high level mechanisms such as community formation, speciation or evolution.

<sup>1</sup> <http://sites.google.com/site/ecosimgroup/research/ecosystem-simulation>

## Our model

To observe phenomena at the evolutionary scale that affect the individual behaviors, several constraints need to be fulfill: (1) every individual should possess genomic information that will be the subject of the evolutionary process; (2) this genetic material should affect the individual behavior and consequently its fitness; (3) it has also to be transmitted and modified from generation to generation; (4) a sufficiently high number of individuals should coexist and their behavioral model should be sophisticated enough in order that complex interactions and organizations could emerge; (5) a model for species representation and an speciation mechanism, leaning on the genomic and behavioral model, has to be defined; (6) for speciation events to occur and new co-adapted behavioral models to emerge and in turn affect the whole system, a large number of time steps need to be performed. We therefore face a computational challenge for both memory management and computational power. We need a model which allies the compactness and easiness of computation with a high potential of complex representation.

We have used a modified version of the Fuzzy Cognitive Map (FCM) model (Kosko, 1986) and adapted it to our problem. This model is used at the same time as the behavioral model of our agents (our individuals) and as the vector of transmission of the evolutionary information. It allows a combination of compactness with a very low computational requirement while having the capacity to represent complex high level notions. Therefore, each agent can possess its unique proper FCM, which is an inherited modified combination of the ones of its two parents. The system can still manage several hundreds of thousands of agents simultaneously with reasonable computational requirements.

The FCM contains sensitive concepts such as: predatorClose, foodClose, mateClose, energyLow; internal concepts such as: fear, hunger, sexualNeed, curiosity, satisfaction; and motor concepts such as: escape, searchForFood, socialize, eat, breed. It includes also weighted links representing the mutual influences of these concepts. Our simulation implements a speciation mechanism related to the genotypic cluster definition (Mallet, 1995). A species is a set of individuals associated with the average of the genetic characteristics of its members. A species split if the difference between the FCMs

of the two most dissimilar agents is greater than a threshold (Aspinall, 2010) leading to two sister species that rapidly diverge to become genetically isolated with no more interbreeding events. Since species membership is evaluated at each time step, a species can emerge or extinct at any time. A typical run last several tens of thousands of time steps, each time step being the time needed for each agent to perceive its environment, to use its behavioral model to make a decision, perform its action, to update the species and the world parameters. In total, more than one billion of agents will be born and several thousands of species will be generated, which allows the evolutionary process to take place and new behaviors to emerge reacting to a constantly changing environment. In addition, a food chain consisting of three levels, primary producers, predators and preys, has been implemented allowing complex interactions between agents and co-evolution to occur.

## Results

### Species abundance distribution

To validate EcoSim, we have compared the ecological patterns it generates with those observed in natural ecosystems (Devaurs, 2010). We have focused on species abundance patterns as they are a key component of ecological theories. To analyze them, we used Fisher's logseries, since it is one of the most classical models of species abundance distribution. The following results, well established in the ecological literature, are also observed in the communities generated by our simulation: the logseries presents a good fit to the distributions of small samples; it fails to do so for large samples and complete community; the logseries performs better on species-rich communities. Even though the logseries does not provide a good fit for large samples, the distribution patterns observed in our communities are very similar to those observed in nature. Thus, at any level, our simulation gives coherent results in terms of relative species abundance.

### Chaotic behavior

Any attempt to model a real system needs to have the capacity to generate patterns as complex as the ones of the real system. We have studied the properties of the time series representing the variation of the number of: preys, prey species, predators and predator species (Golestani, 2010). We examined whether a chaotic behavior exists in these signals. To enforce our results, we use four different methods: Higuchi fractal dimension, correlation dimension, largest Lyapunov exponent, P&H method. To obtain a statistically significant evaluation, we apply the surrogate test method on 24 samplings of these data. All of them providing clear predictions that the behavior of simulation is deterministic chaotic.

### Population spatial distribution

We have conceived a measure to compute the spatial center of a population in a torus world (Sina, 2011). Computing spatial distribution in an ecosystem simulation is important for analyzing various aspects of species or group of individuals.

One of the applications is prediction of extinction of a population. When individuals of a population are dying, their spatial distribution either globally or locally, starts to decrease; since it has a relationship with number of living individuals of the population. Also it was shown, as expected in the parapatric model of speciation that genetically similar individuals in a population tend to live closer to each other.

## Conclusion

This project is at its early stage but we have already many interesting results. We have submitted several papers: diffusion and mitigations of diseases in an ecosystem, a machine learning approach for modeling species abundance distribution, the natural selection effect on the variation of the ecosystem's complexity, and the multifractal properties of the individuals' spatial distribution. We are currently working on: the effect of reduction of gene flow on the rate of speciation, the emergence of new complex behaviors and their effect on fitness, applying machine learning techniques to predict species extinction and speciation events, the effect of choice of mating partner on variation of the population's fitness and the effect of multiple food resources on emergence of species.

## Abstract

Cultural evolution occurs through the transmission of cultural traits, and we consider the meme as the unit of cultural transmission. We construct an agent-based model representing the processes by which cultural transmission occurs and to link these to the community-scale phenomena arising from agent interactions. We base our model on small communities of e-Puck robots, and following work on movement-based memes, consider sound as the medium of cultural transmission. Our architecture affords (re)production of memes, variation in meme production and a range of meme selection and meme memory strategies. Through these processes, we identify the meme complexities, meme memory strategies, meme selection strategies and e-Puck movement speeds that promote and inhibit both meme diversity and reproductive fidelity.

## 1 Introduction

Human and animal decision-making is strongly influenced by knowledge acquired through observation of the behaviour of others, and when behavioural patterns are spread among individuals over generations this is a form of cultural evolution (Danchin et al., 2004). Thus cultural evolution occurs through the transmission of cultural behaviours / traits (Christensen and Kirby, 2003). Agent-based models seek to understand the processes by which cultural transmission occurs and to link these to the community-scale phenomena observed when groups of agents interact (Buzing et al., 2005). By understanding these processes at the individual scale it is possible to manage change at the community scale (Bown et al., 2007). To effect cultural change is a challenging problem and it is possible to progress by taking inspiration from biological systems (Danchin et al., 2004).

One view of cultural evolution is to recognise a correspondence between the processes underlying cultural and biological evolution: variation, reproduction, natural selection (Heylighen and Chielens, 2008). Rather than genetic transmission and recombination with variation as the mechanism of reproduction, cultural evolution considers the meme (Dawkins, 1976) as the unit of cultural transmission, i.e. communication. Memes may be transmitted and recognised by individual agents in the community. Variations may occur through errors in interpretation. Natural selection occurs since some memes are fitter than others: i.e., some memes are more likely to be communicated than others

(Heylighen, 1999). Thus, biology offers a framework for studying cultural evolution (Speel, 1995). However, cultural studies face the same problems as biological ones: it is impossible to measure everything and real-world complexity is overwhelming (Humphreys 2007).

To make progress, many social science experiments take a problem-led view of social behaviours, focusing on specific issues and building in assumptions about societal functioning to support analysis of the question posed, e.g., in emergent cooperation and communication (Buzing et al. 2005) and in language (Christiansen and Kirby, 2003). In Buzing et al. (2005), for example, results show that cooperation pressure leads to the evolution of communication skills that support cooperation. This cooperation pressure is built into the model, in that resource acquisition is directly enabled by cooperation. Communication is likewise built in, enabling recruitment of cooperators to acquire resource. Importantly, the model allows flexibility in the extent to which agents use communication – talking to request cooperation and listening to respond to cooperation requests – to interact with other agents. The work demonstrates the impact of environment (cooperation pressure) on communication strategy, and that the ability to listen occurs in advance of the ability to talk. Such a problem-led view thus focuses model construction on factors (measurables) and system dynamic assumptions that are likely to contribute to the phenomenon being investigated. While this approach limits the scope of the model to the question asked, it does provide insight into that question. Moreover, model results serve to refine the real-world question being set and direct iteratively the next phase of experimental design (Christiansen and Kirby, 2003) so focusing data collection on those measurables, and this in turn can refine the model construction (Bown et al., 2007).

Here, we take an alternative, complementary approach, where no assumptions are made about societal functioning and the goal is to elicit the fundamental processes responsible for the development of a proto-culture. This is similar in approach to Kirby (2001) where a protolanguage, lacking any structure, gives rise to a syntactic structure through evolution of the language itself rather than through evolution of the users of that language. Here, we outline an artificial culture laboratory designed that affords (re)production of memes, variation in meme production and a range of meme selection strategies. Through these fundamental processes, we are able to identify conditions that promote and inhibit both meme diversity and

reproductive fidelity. Our artificial culture lab comprises a physical arena with closed boundaries, populated by two-wheeled mobile robots called e-pucks, capable of moving forwards, moving backwards and turning (Mondada et al., 2009). They are equipped with a range of sensors that enable detection and tracking of obstacles and other robots. Importantly, robots can sense and track the movements of other robots nearby. Robots can signal to each other with movement and light (through programmable LEDs), and both movement and light may be detected through a simple on-board camera. Robots can also signal to each other through sound, as each has an on-board speaker and microphone. This allows multi-modal communication strategies on a one-to-one or one-to-many basis, and with or without active consent (i.e. one robot can eavesdrop on the communication between two others). The artificial culture lab is fully instrumented. A tracking system allows the movements of all robots to be captured and recorded for analysis and interpretation. The e-pucks have linux board upgrades (Liu & Winfield 2010).

We have implemented two modes of robot-to-robot communication: movement and sound. In each case, memes are the unit of cultural transmission. Our longer-term goal is to integrate movement-meme and sound-meme communication and investigate the evolution of multi-modal communication strategies. We have already published our movement and we detail sound-mediated communication here. For movement, memes are self-contained movement sequences (Winfield and Erbas, 2011). We refer to the robots as copybots (Blackmore, 1999) since they have no behaviours other than imitation, alternating from learner to teacher. While a teacher robot, seeded with one or more initial memes, enacts its meme, one or more learner robots observe that meme and store it in memory. When learner becomes teacher, a meme is selected from memory and enacted while other learner robot(s) observe. Importantly, we preclude robot-to-robot telepathy: the learner robot learns the meme enacted by the teacher through its senses alone. Consequently learners must solve the correspondence problem (Nehaniv and Dautenbaum, 2007), i.e. the problem of translating perceptions of another's actions (via sensory input) into corresponding motor actions.

The use of real physical robots, rather than simulated robots, together with the preclusion of robot-to-robot telepathy increases potential for emergence in behaviour, and in Winfield and Erbas (2011) we demonstrate that embodied movement-meme evolution is possible in the artificial culture lab. A combination of imperfect sensors, distance-dependent errors in sensor input and shared channels of communication provide a form of natural variation that drive novelty in the meme set. Specifically, artefacts emerging from this variation may give rise to new memes – and so new cultural “traditions” – that occur for no other reason than that they can (Winfield and Griffiths, 2010). For sound-memes, generated through e-puck speakers and heard through e-puck microphones, we also adopt the copybot concept. E-pucks move around an arena, listen to sound-memes sung by other e-pucks and then imitate what has been heard, under different meme selection strategies. Of note is that we were required to resort to simulation for our sound-meme experiments because

of practical limitations, particularly in regard to sound detection. With regard to sound generation, the e-pucks were not able to generate a consistent frequency. Moreover, the amplitude produced was very sensitive to battery level and so we had a very short operating window. With regard to sound detection, the e-pucks are very sensitive to: direction, needing to be directly facing the sound source under idealised (sound-proofed) conditions; distance, with a sharp distance-dependent attenuation; and ambient noise, with the noise created by e-puck movement being particularly problematic. The battery and directional constraints are removed in the simulator. Inconsistency in frequency of sound generation, i.e., natural variation, and the distance-dependent attenuation are accommodated in the simulator. We undertook systematic *in vitro* experiments to characterise that natural variation and then parameterise the simulator based on those experiments as in previous ecological studies (Bown et al. 2007). Ambient noise is eliminated by our use of simulation. The benefits of working with real robots are made clear in Winfield and Griffiths (2010), and the best compromise was to capture the natural variation through isolated robot-to-robot communication experiments and then develop software models of that variation. We are then able to integrate this sound-meme model into the real-world movement-meme robot laboratory to effect (a best approximation to) a system to explore the evolution of multi-modal communication.

## 2 Methods

### 2.1 Simulator Overview

The simulator was designed to simulate a number of e-puck robots moving around the Artificial Culture Lab, listening to and imitating each other's songs.

The simulator was designed to be a high-fidelity simulation of the transmission, detection and analysis of sound, and consequently we carefully calibrated the sound dynamics using real robots and these dynamics set the time step of the simulator (section 2.2). Our treatment of space and robot movement is of lower fidelity, yet designed to map onto the Artificial Culture Laboratory (section 2.3). In addition to the memory selection strategy described in Winfield and Erbas (2011), we explore alternate selection strategies (section 2.4) and the impact of these strategies on meme propagation in communities of robots (section 2.5).

### 2.2 Real-robot Calibration Experiments and Simulator Parameters

Extensive experiments were carried out to measure the sound signal generation and detection capabilities of the (real) e-pucks for simulator calibration. We identified a decay function for sound attenuation, the range of frequencies that could be both generated and detected by the e-pucks, a statistical model of variation in frequency generation, and upper and lower limits on speed of movement.

*Sound attenuation over distance* – the ability of e-pucks to

detect sounds generated by other e-pucks was measured over increasing distances. This is used to reduce the amplitude of the sounds over distance, ensuring that distant sounds are quieter and closer sounds are more readily detected.

*Inconsistent frequency* – e-pucks may be programmed to generate sounds at specific frequencies; however hardware limitations preclude generation of a clear, consistent tone. We measured variation in frequency generation over a range of frequencies (500Hz to 3200Hz). We then constructed a linear regression model to describe the average variation in for each frequency in that range in 100Hz intervals.

Figure 1 – Frequency Variation; Inset Sound Attenuation

Vertical line shows the target frequency of 2000Hz. The distribution curve shows the variation of the actual frequency generated by the e-Puck.

$$\text{MeanFrequency} = -16.8243 + (1.01247 * \text{TargetFrequency})$$

$$\text{StandardDeviation} = 46.9$$

The simulator samples from this distribution for every generated sound. Fig. 1 above shows the frequency distribution for target 2000Hz.

*Time-step and sound sampling rate* – e-pucks sample sound at 33kHz. Allowing for the (measured) time to transfer the samples from PIC to Linux processor (4ms) and 4ms processing time, e-pucks can process 128 samples every 8ms. The time-step in the simulator is set to 8ms. 128 samples gives the best ratio accuracy of frequency and timing measurement and gives a good range of usable frequency bands. More samples would decrease the timing measurement accuracy for little gain as the variation in frequency is greater than the increased accuracy of identified frequency ranges.

## 2.3 Simulation of Space and Memes

*The Simulated World* – the arena of the Artificial Culture Lab is represented by a lattice. The edge of the grid is a non-toroidal boundary. Each lattice cell represents an area approximating the size of an e-puck (5cm x 5cm). Each square may only be occupied by a single e-puck. Movement is represented by transitions from one square to an adjacent, unoccupied square, happening once every  $n$  milliseconds, where  $n$  is determined by the speed of the e-puck (note, the resulting simulated speed of the e-pucks is within the range of real e-puck speed). E-pucks move in straight lines, reflecting off lattice edges. When an e-puck attempts to move into a square occupied by another e-puck – i.e. a collision – it instead changes direction and moves to the first unoccupied

square in a clockwise direction, with respect to itself, from the occupied square, and if surrounded it does not move. The e-pucks are positioned centrally in the cell; consequently, for sound attenuation the distance between two e-pucks is equivalent to the distance between cell centres. E-pucks do not move if they are imitating or listening to other e-pucks. Note, a given e-puck may hear a single song, or multiple songs and this can result in interference.

*Memes* – a meme is, in the simulation, the representation of the song. Memes are mono-tonal, and the frequency that the meme is sang at is determined by the particular e-puck singing the meme. A meme is made up of a series of pulses of sound separated by periods of silence, and these are termed pulses of sound and pulses of silence respectively. The description of a meme, then, at its simplest is a list of pulse lengths (alternating periods of sound and silence) in milliseconds.

Here, the “idealised” form of a meme has been defined as a series of pulses of equal length. An idealised meme of three 250ms pulses of sound separated by 250ms pulses of silence would therefore be described as 250,250,250,250,250. Errors in transmission, detection or analysis of sound could result in a non-idealised meme described as 250,400,150,150,250.

*Memory: Distinct and Grouped* – to investigate different strategies of memory and selection, memory may be distinct or grouped. An e-puck with distinct memory will store every meme heard as a new meme, even if it is identical to a meme already in memory. An e-puck with grouped memory will examine every meme heard and determine if it is already known, in accordance with criteria defined below, or new. New memes are added to memory; already known memes have their count incremented.

*Memory: Short-term and Long-term:* - within the simulator the e-pucks have the equivalent of both long and short term memory. Short term memory stores the memes that have just been heard while long term memory stores all the memes that have been heard during the simulation run. While the e-puck is hearing sounds, those sounds are used to build up memes in the short term memory. When the e-puck hears silence for more than two seconds all the memes in short term memory are finalised, the e-puck decides which meme to sing next (from short or long term memory, depending on strategy), and copies all the memes from short term to long term memory.

## 2.4 Meme Description and Selection Strategies

*Meme* – a meme is a number of pulses of sound and silence. In its idealised form all pulses are the same length.

*Meme Metric* – we define a single metric comprising three measures: total meme length, in milliseconds; number of pulses in the meme; and a measure of the structural difference between the meme and an idealised meme of the same length and number of pulses.

$$\text{Structure} = \ln \left( \sqrt{\sum_k (\text{PulseLength}_k - \text{IdealisedPulseLength}_k)^2} \right)$$

Meme similarity is directly proportional to the Euclidean distance in the three-dimensional metric space.

Two memes are judged to be similar enough to be considered the 'same meme' if they have a) the same number of pulses, b) the same overall length to the nearest 500ms (one perfect pulse) and c) both structural measures are either below or above 6.214 (derived from perfect pulse).

*Selection Strategies* – here, we examine 4 different strategies for selecting which meme to imitate in response to a meme being heard.

1. *Random Mimicry* – after hearing a meme (or multiple simultaneous memes), add it to memory. When imitating, randomly pick a meme from that memory and sing it. This is a form of indirect mimicry. The e-puck does not mimic what it has just heard, it mimics something that it has heard at some point. Selection is weighted by how often the meme has been heard.

2. *Direct Short-term Mimicry* – the e-puck mimics one of the memes it has just heard, those which are in short term memory, picking randomly from those memes if more than one was heard. Selection is thus unaffected by the memes in long-term memory (which are stored for auditing).

3. *Direct Long-Term Mimicry* – the e-puck compares the memes it has just heard to the memes in its long term memory, determines which newly heard meme is most similar to one of the memes already in memory and mimics that heard meme. This is direct, memory-driven mimicry.

4. *Proto-Imitation* – the e-puck compares the memes it has just heard to the memes in its memory, determines which heard meme is most similar to one of the memes already in memory and sings the known meme from its memory. (most similar is closest in Euclidean distance in the three-dimensional metric space) A distinction can be made between mimicry, the copying of actions, and imitation, recognising the intent of those actions and enacting that intent. With this latter strategy the e-puck differentiates between the meme that it heard (the *action*) and the meme it believes the singer was trying to sing (the *intention*) and sings that intended meme in response. This is simple, proto-imitation rather than basic mimicry.

## 2.5 Experiments

The distance-dependent sound attenuation and inconsistency in frequency generation introduce potential differences between memes sung and memes heard. Moreover, when this is combined with e-pucks both singing and moving concurrently, new memes may emerge. New memes may arise from memes that: overlap, such that silences in one meme are filled with sounds of another; concatenate, since there are no special signals at the beginning or end of a meme it is possible to blend memes over time; and are generated with errors, through the model of inconsistency. The resulting complexities require us to first analyse meme evolution patterns in general (experiment 1). We also explore under what circumstances meme propagation is best effected (experiment 2).

*Experiment 1 – Meme evolution* – the impact of meme memory (distinct and grouped) and selection strategies on meme evolution was explored. The e-pucks were initialised with a set of four seeds in memory: i) five pulses of 300ms, ii) five pulses of 500ms, iii) five pulses of 700ms and iv) five pulses of 900ms. The other parameters varied across the tests were speed (eight speeds from stationary 0, to fastest 7) and population size (1 to 8 e-pucks). This resulted in 256 distinct tests, each of which was run multiple times.

We have devised “Memeographs” to report on these experiments. Our memeograph is a hierarchical graph that shows the connections between memes sung and memes heard. It identifies the individual robots involved, memes that are repeated and distinguishes between original seed memes and new memes. Nodes are memes and links are “listening events”. For a given link, the meme at the arrow end was heard (and added to memory) as a result of hearing (or mishearing) the meme at the tail end. While the memeograph contains time-based information, it should not be misinterpreted as a time-line; in particular, a chain of memes should not be taken as evidence that a meme was sung multiple times in a row – it is possible that that chain was sung intermittently with other memes being sung in between. The colour of the node indicates the meme. Node shape indicates the robot. Seed memes are depicted larger than new memes.

*Experiment 2 – Meme Propagation* – We examine the propagation of a single meme from a single e-puck across a community. Initially, one e-puck knows a single meme; seven other e-pucks begin with no memes in memory. Consequently, these e-pucks construct their memories from this seed meme only when they encounter and hear that meme, or some corrupted form of that meme. We analyse under varying conditions the rate of meme propagation. The experiments were replicated fifty times for each memory / selection strategy pairing at eight different speeds (0 to 7). We varied seed meme complexity: the shortest meme consisted of three 500ms pulses (sound, silence, sound); other seed memes were two pulses longer (5, 7, 9, 11 13, 15 and 17 pulses).

## 3 Results

### 3.1 Meme Evolution

Memeograph topology is predominantly affected by memory strategy and selection strategy. Speed had no effect on diversity, except for zero speed which precluded meme exchange and therefore evolution. Diversity scales linearly with population size (results not shown). For illustration we show four of the possible eight combinations below (Fig. 2). For each memory and selection strategy combination, we use the Random Mimicry selection strategy as a baseline to express the average number of memes and clusters of memes, determined by QT Cluster Analysis (Heyer et Al, 1999). The QT Cluster Analysis is based on the metric described in 2.4, normalised to a 0.0 to 1.0 range, with a radius of 0.05 and a

minimum cluster size of five.

	Memory Strategy			
	Grouped		Distinct	
Selection Strategy	Clusters	Memes	Clusters	Memes
1. Random Mimicry	1	1	1	1
2. Short-term Direct Mimicry	0.91	1.02	0.64	0.90
3. Long-term Direct Mimicry	0.94	1.0	0.66	0.80
4. Proto-Imitation	0.98	0.98	0.75	0.81

Table 1 - Meme Evolution Results

Table 1 shows the relative numbers of memes and clusters (groups of memes) by selection and memory strategies

**Grouped Memory** - Memeographs of grouped memory experiments indicate how often a given link has happened with a number on the link and by the thickness of the link line. Grouped memory results in fewer memes in memory and fewer clusters than Distinct memory. Table 1 above shows the relative sizes of the number of memes and groups of memes generated by the different memory and selection strategies.

1. *Random Mimicry* – This is the base line case for Grouped Memory strategy, it produces more clusters and memes than any other selection strategy (when using grouped memory).
2. *Direct Short Term Mimicry* – (Fig. 2b). For the grouped memory strategy, the Direct Short Term Mimicry selection strategy produces the least clusters of all the selection strategies. This is because the mimicry is only based on the memes most recently heard, limiting the number of memes that could be sung at any point. There is an increasing chance that the memes just heard will already be in memory.
3. *Direct Long Term Mimicry* - Comparing the memes heard to the memes in memory has the effect of increasing the number of memes involved in the mimicry, resulting in more diversity of memes than the short term mimicry.
4. *Proto-Imitation* - results in slightly fewer clusters and memes than the Random Mimicry strategy. Singing a meme heard earlier rather than the meme just heard increases the likelihood that the meme sung will be different to the heard meme.

**Distinct Memory** – With every meme stored as a distinct meme this strategy produces 47% more clusters and 755% more memes than the grouped memory strategy.

1. *Random Mimicry* – all memes in memory are equally likely to be chosen, and over time most memes will be sung multiple times. This is the base

line case for Distinct Memory strategy.

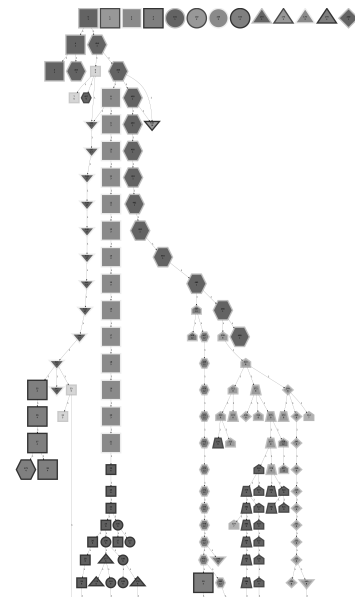

Figure 2a – Direct Memory, Direct Short-term Mimicry

Figure 2b – Grouped Memory, Direct Short-term Mimicry

Each node identifies a meme in the memory of an e-puck. The shape of the node identifies the e-puck, the colour identifies the meme and the size distinguishes between seed memes (large) and emergent memes (small).

2. *Direct Short Term Mimicry* – Since each meme heard is stored as distinct meme in memory, long chains of nodes with the same shape and colour occur (Fig. 2a). This combination reduces the number of clusters more than any other strategy but does not reduce the overall number of memes as much as Direct Long Term Mimicry and Proto-Imitation.
3. *Direct Long Term Mimicry* – results in almost as low a number of clusters as Direct Short Term Mimicry but with far fewer memes stored.

4. *Proto-Imitation* – this too is a very limiting strategy though the effect on the memeograph is completely different. With this strategy, only seed memes are ever sung. Whatever the listener hears it interprets it as a prompt to sing a seed meme, as such no newly heard meme is ever more than one step away from a seed meme.

Using Random Mimicry as a baseline the other strategies reduce the number of clusters found for both memory strategies, with a larger reduction for the distinct memory strategy. They do not change the overall number of memes generated with the grouped memory strategy as they do with the distinct memory strategy. This is interpreted as the selection strategies having the effect of implicitly grouping the memes, explaining why this effect of the selection strategies is greater when the memory strategy does not group the memes (i.e. Distinct Memory).

Figure 3 – Memeograph Detail – Grouped Memory

Each node identifies a meme in the memory of an e-puck. The shape of the node identifies the e-puck, the colour identifies the meme and the size distinguishes between seed memes (large) and emergent memes (small).

a & f – two distinct memes, each known by multiple e-pucks

b, c & g – emergent memes created by incorrect mimicry of memes

d & e – two different e-pucks incorrectly mimicking meme c

A closer inspection of the memeograph affords an account of experiment dynamics, as depicted in the fragment shown in Fig. 3. In area a, the large shapes show a seed meme is mimicked successfully (nodes have same colour) by four robots (different shapes). Examination of the whole memeograph (not shown) reveals that meme is a stable meme that is sung and heard correctly often.

However it is not mimicked correctly every time: the three small shapes in areas b and c are coloured differently indicating that either the imitator sang the meme badly, or that the listener misheard, perhaps by not hearing the start of the meme.

Interestingly the small triangle (area c) was heard by two

other robots, diamond (d) and square (e), both of which misheard the meme in the same way, as shown by them having the same colour. More interesting still, this misheard meme proves to be a stable successful meme itself and gets passed on to all the other robots in the experiment (area f).

Selection strategies of Random Mimicry and Long-term Mimicry have more diversity than those of Short-term Mimicry and Proto-imitation (Fig. 4). Speed and meme complexity have no effect on diversity.

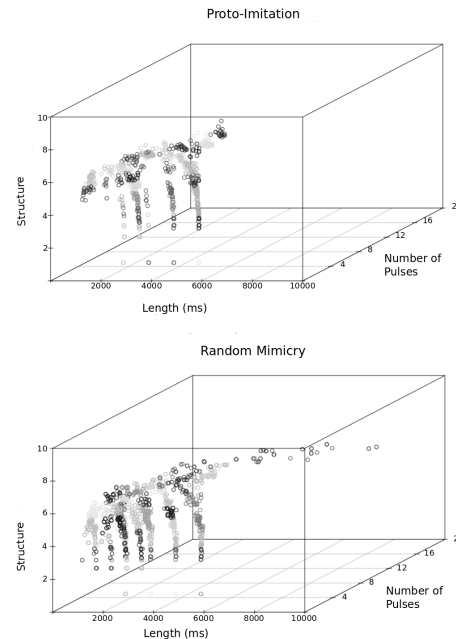

Figure 4 – Homogeneity and Diversity

Two 3d scatterplots of memes, each meme is plotted in three-dimensional space by its metric; the x-axis is the length of the meme in milliseconds, the y-axis is the number of pulses in the meme and the z-axis is the measure of distortion from the idealised form of the meme. The memes are coloured by similarity derived from QT cluster analysis of the data.

### 3.2 Meme Propagation

Fig. 5 shows the average spread across the community of initial seed memes of differing complexity for each of the memory/selection strategy pairs. The x axis shows the speed of the e-pucks. The y axis is number of robots the seed meme has spread to, varying from zero (no propagation) to seven (maximum propagation). As seed meme complexity increases meme propagation decreases: a shorter meme is more likely to be spread throughout the community since there is less chance of making a mistake in a shorter meme or of only hearing part of it.

Memory strategy has little effect on the propagation of the seed meme. In contrast the choice of selection strategy has a marked effect.

*Random Mimicry* – proves to be an effective strategy to propagate the seed meme. It ensures that if a robot has correctly heard the seed meme it has a chance to repeat it (or any other meme) at some point.

Figure 5 – Meme spread by meme length and e-puck speed

Speed varies from 0 (stationary) to 8 (fastest). Memes vary from shortest (1) to longest (8). Spread varies from 0 to 7 (full propagation). Dashed lines above speed 5 indicate speeds the real e-pucks are incapable of.

*Direct Short Term Mimicry* is the least successful at spreading the seed meme. Failing to compare what is heard to what is in memory means that any drift away from the seed meme will only be corrected by chance errors in communication.

*Direct Long Term Mimicry* is a more effective strategy. The more often a meme has been heard the more likely it is to be mimicked, and an error by a single e-puck is likely to be ignored. However by mimicking the heard meme that is closest to a known meme there will inevitably be some incremental drift away from the seed meme. This drift may lead to a meme that is greatly different from the seed meme.

*Proto-Imitation* is another effective strategy. The more often a meme is heard the more likely it is to be repeated. By repeating the known meme that is closest to the heard meme rather than mimicking the heard meme any errors in the heard meme are ignored and the correct version of the meme is sang. This limits the incremental drift problem.

Speed has a significant effect on the spread of the seed meme. If the community is moving too slowly there is insufficient opportunity for meme exchange. For experiments that replicate speeds at which the e-pucks are capable of moving (speeds 1-5) we see that as speed increases there is increased spread of the seed meme, with the greatest increase in spread at the lower speeds and a plateau-effect at higher speeds. To investigate this plateau we simulated the effects of robots that could move faster than the e-pucks (speeds 6+), and observed that at higher speeds meme spread reduces. E-pucks moving

at high speeds are typically hearing only part of memes being sung as they move away from neighbours too quickly. Very short memes (meme 1 and to some extent meme 2) are less affected by the high speed drop off.

## 4 Discussion

We explored sound meme transmission in a simulated community of e-Puck robots. We identified conditions that promote and inhibit both meme diversity in and reproductive fidelity of sound memes in the artificial culture laboratory.

### 4.1 Meme Evolution

The grouped memory strategy, i.e. only storing distinctly different memes as new memes and recording how many times each meme had been heard, resulted in fewer memes than distinct memory, i.e. storing every meme heard as a distinct meme. Grouped memory also results in fewer meme clusters and therefore a more homogeneous set of memes.

Grouping memes eliminates small mutations in the memes that the distinct memory approach keeps. Consequently, meme evolution occurring in small steps through multiple imitations (iterations) is precluded. As a result, changes that are observed occur from larger meme mutations, resulting in distinctive memes occurring at much lower frequency.

Short-term direct mimicry, i.e. mimicking one of the memes that has just been heard without any reference to other memes in long term memory is a conservative strategy. Compared to the other selection strategies, this results in the fewest clusters and therefore less diversity. If, at any point, a single meme is more commonly sang than any other then it is likely to remain the most common meme sang (since the chance of randomly selecting it increases as more e-pucks sing it). A very different meme is therefore less likely to be mimicked and one off errors in singing or listening will have little effect on the system.

In contrast, random mimicry maximises diversity in memes. The random responses greatly reduce the chance that the e-pucks will synchronise on a single meme, and allows one off memes that the other strategies would ignore a chance to propagate.

The effect of allowing long-term memory to influence imitation, through long term direct mimicry or proto-imitation, is to reduce diversity. Short-term mimicry is driven by the pattern of the most recently heard memes, increasing the chance that the e-pucks will synchronise the memes they are singing, resulting in fewer distinct memes and more homogeneity. Long term memory does though have a greater effect on reducing the overall number of memes in the system. To maximise diversity, a combined strategy of distinct memory with random mimicry is best. To minimise diversity, a strategy of grouped memory with short-term direct mimicry is optimal. Note, diversity scales linearly with population size and not at all with speed, apart from speed zero which limits exchange and effectively precludes meme evolution.

## 4.2 Propagation

In addition to the impact of meme selection strategy, detailed at length in section 3.4, the successful propagation of specific memes among the e-Puck population varies in accordance with meme length, meme complexity and speed of movement. Meme length and complexity impact successful meme propagation. Short, simple memes propagate through the community more successfully than longer, more complex ones and are less likely to be truncated or misheard, and during a fixed time period, shorter memes can be repeated more often and are more likely to be heard throughout the community.

Speed of movement also affects meme propagation. If the e-Pucks are not moving at all then there is limited or no opportunity for propagation: any e-Puck out of ear-shot from the others will never receive the meme. For any but the shortest memes, moving too quickly has a limiting effect on propagation, fast e-Pucks seldom hear the full meme.

In summary, to propagate a specific meme the best approach is for a simple meme with the robot moving at an average speed using any strategy except short term mimicry. Moreover, to propagate a specific meme while keeping diversity as low as possible - and so to maximise the impact of that seed meme - the grouped memory and long term, direct mimicry strategies should be used.

## 4.3 Conclusions

We focused on sound memes and used a similar experimental approach to our work on movement-memes (Winfield and Erbas, 2011), which reported embodied movement-meme evolution. Because of limitations in the e-Puck platform, we had to recourse to simulation but we encapsulated the observed natural variation in e-Pucks through model parameters. Here, as in Winfield and Erbas (2011), we demonstrate that meme selection strategy, when combined with natural variation and reproduction through imitation, is a crucial factor in cultural evolution.

Much progress has been made in evolutionary biology and we, like Mesoudi et al. (2006), believe that much progress can be made in cultural evolution by adopting methodologies from biology. We propose that our artificial culture lab provides a real-world framework with natural variation for controlled experimental simulations in embodied, multi-modal cultural evolution. We can explore meme-gene coevolution (Bull et al., 2000), the influence of environmental variation on selection (Kingsolver et al., 2003), and the links between micro- and macro-evolution scales. Kline and Boyd (2010) note that larger populations generate more complex cultural adaptations than smaller, isolated ones. In their review they indicate that chance events that perturb cultural transmission are more impacting in small populations. Moreover, errors in transmission will cause complex traits to degrade more quickly than simple traits, although large populations mitigate this. As a complement to such empirical studies, our experimental framework allows exploration, in a controlled way, of group selection processes (Boyd and Richerson, 2010) in the context of individual variation. We can thus investigate

the relation between individual decision-making and community-scale cultural phenomena.

## Abstract

A flock, school, and swarm are collective behaviors that can be compared to a human consciousness or body. Through recent developments in image analysis and model simulation, it has been found that the collective behavior of animals can, as a whole, show characteristics of a single “body”. It has also been found that intrinsic noise can positively contribute to swarming and/or flocking. Motivated by field observations of soldier crabs, *Mictyris guinotae*, we propose a swarm model based on inherent noise and back propagation in time that mimics mutual anticipation. A swarm generated by this model is characterized by flexible, dynamical and robust behavior containing inherent turbulence. We demonstrate that the model can produce water-crossing, hourglass and logic gate behaviors, which are also found in real soldier crabs. We describe how a sense of ownership and a sense of agency of the “body” arise in our model, and we propose that the concept of a body should be verified in terms not of stability but of robustness.

## Introduction

Does a swarm, flock or school have a single consciousness or body (Vicsek, 2001, Couzin, 2007; 2008; 2010, Sumpter, 2010)? This question has been addressed in the context of collective decision making by computer models, particularly BOIDS (Reynolds, 1987) and SPP (Vicsek et al., 1995, Czirók et al. 1996). Owing to developments in image analysis that have made it possible to obtain kinetic data on the movements of real organisms (Ballerini et al., 2008a, b, Carere et al., 2009), several internal dynamical structures within groups have recently been identified. These structures include topological distance (Ballerini et al., 2008b), scale free correlation (Cavagna et al., 2010) and inherent noise (Yates et al., 2009). This research also suggests that inherent turbulence could play an essential role in collective motion. The collective behaviors of animals might be based on inherent noise, and the internal structures of a group are perpetually generated and modified to maintain a robust unity as a whole.

A flexible but robust swarm (flock or school) can be compared to a human’s body (Gunji et al., 2010). In this sense, an animal group might recognize external objects in the

environment by an embodied cognitive process (Varela et al., 1992, Pheifer and Scheier, 2001, Pheifer et al., 2007). Human body awareness can be described by a sense of ownership (i.e., the sense that I am the one who is undergoing an experience) and of a sense of agency (the sense that we are the initiators of our actions) (Wegner et al., 2004, Tsakiris, et al., 2008). Although a body appears to be very stable and unambiguous, it is well known that synchronous visuo-tactile stimulus can make body illusions, such as the rubber hand illusion (Botvinick, M. and Cohen, 1998) and an out-of-body experience (Lenggenhager et al., 2007, Ehrsson, 2007) possible. The body is also a robust and flexible system that can be adapted to environments. The problem still remains whether a swarm, flock and school can be compared to a “body” in these senses.

Here, we show how inherent noise in conjunction with organisms’ mutual anticipation can actively contribute to the generation and maintenance of a robust swarm in a computer model. Mutual anticipation was implemented by asynchronous updating and back propagation through time. The time slice of a swarm is thus so complex that a swarm is robustly maintained and contains inherent turbulence. The model was constructed through observations of soldier crabs, *Mictyris guinotae* (Bradshaw and Scoffin, 1999, Shih., 1995, Peter et al., 2010). Our model can reproduce a swarm entering and crossing water through the emergence of a highly concentrated subpopulation driven by inherent turbulence; an hourglass of crabs showing regular oscillations; and collision-based-computing logic gates implemented by a swarm ball. The generation of these behaviors depends on the robustness and flexibility of swarming. Finally, we argue that a body-like character is embedded in our swarm model in the form of the interplay between anticipation and memory.

## Swarming by mutual anticipation

Through observations of soldier crabs in the Iriomote Islands, Okinawa Prefecture, Japan, we discovered a role for inherent turbulence in collective behavior. A swarm of soldier crabs always contains inherent turbulence such that individuals in a swarm have different velocities, while the swarm maintains a coherent and dense unity. Inherent

turbulence in particular plays an essential role in water-crossing behavior. When a small swarm of soldier crabs confronts a water front, it cannot enter the water and moves along the perimeter of the water pool. In moving along the water front, inherent turbulence creates a highly concentrated locus inside the swarm, which can then enter and cross the water.

If inherent turbulence provides the essential mechanism to generate robust collective behavior, an important question is whether this robustness can be distinguished from stability. In the context of stability, perturbations conflict with the mechanism that generates order. In the context of robustness, inherent noise positively contributes to the generation of collective behavior. To implement inherent noise, we proposed a mechanism of mutual anticipation based on multiple potential transitions.

### Basic model

A model is defined in a discrete space of  $S \times S$  with  $S = \{1, 2, \dots, S_{\text{MAX}}\}$ . The co-ordinate of the  $k^{\text{th}}$  agent at the  $t^{\text{th}}$  step is given by

$$P(k, t) = (x, y) \quad (1)$$

where  $x \in S, y \in S$ , and  $k \in K = \{1, 2, \dots, N\}$ . Each  $k^{\text{th}}$  agent at the  $t^{\text{th}}$  step has  $P$  number of potential vectors  $v(k, t; i)$  with  $i \in I = \{0, 1, \dots, P-1\}$ . If  $i = 0$ , the vector is  $v(k, t; 0)$ , which is known as the principal vector. Otherwise, the vector is represented by the angle  $\theta_{k,t}$ , such that

$$v(k, t; i) = (\text{Int}(L\eta_i \cos(\theta_{k,t} + \xi_i)), \text{Int}(L\eta_i \sin(\theta_{k,t} + \xi_i))) \quad (2)$$

where for any real number  $x$ ,  $\text{Int}(x)$  represents integer  $X$  such that  $X \leq x < X + 1$ .  $L$  is the length of principal vector. Because of the wrapped boundary,  $X$  belongs to  $S$ . If  $i \neq 0$ , random values  $\eta_i$  and  $\xi_i$  are selected with equal probability from  $[0, 1]$  and  $[-\alpha\pi, \alpha\pi]$ , respectively. The target of the vector is represented by  $\alpha(k, t; i) = P(k, t) + v(k, t; i)$ .

The mutual anticipation depends on the popularity of a site,

$$\zeta(x, y; t) = \begin{cases} |\{\alpha(k, t; i), k \in K, i \in I \mid \alpha(k, t; i) = (x, y)\}|, & \text{If } \forall (k \in K) P(k, t) \neq (x, y); \\ 0, & \text{otherwise.} \end{cases} \quad (3)$$

$\zeta(x, y; t)$  represents the number of potential transitions whose targets reach the site  $(x, y)$  where there is no agent. Before updating the location, for any  $(x, y)$  at the  $t^{\text{th}}$  step and  $\omega(x, y; t) \in \{0, 1\}$  we set  $\omega(x, y; t) = 0$ .

The agents' locations are updated asynchronously. If there exists  $i \in I$  such that  $\zeta(\alpha(k, t; i)) \geq 2$ , the next site for the  $k^{\text{th}}$  agent is defined by

$$P(k, t+1) = \alpha(k, t; s), \quad (4)$$

where  $s$  satisfies the condition such that for any  $i \in I$ ,  $\zeta(\alpha(k, t; s)) \geq \zeta(\alpha(k, t; i))$ . These conditions ensure that an agent moves to the most popular site. If multiple sites satisfy this condition, one is chosen randomly. Because the popularities are propagated backward in time, agents in a swarm can anticipate each other's moves.

A set of updated sites is represented by  $U_N = \{(x, y) \in S \times S \mid P(k, t+1) = (x, y)\}$ . The vacated site generated by equation (4) is recorded in memory as  $\omega(x, y; t) = 1$  if  $P(k, t) = (x, y)$  and  $P(k, t+1) \in U_N$ . An agent that is not updated by equation (4) then moves to the vacated site by

$$P(k, t+1) = \text{Rd}\{(x, y) \in N_f \mid \omega(x, y; t) = 1\}, \quad (5)$$

if  $|\{(x, y) \in N_f \mid \omega(x, y; t) = 1\}| \geq 1$ , where  $\text{Rd}J$  represents an element randomly chosen from set  $J$ , and  $N_f$  is the follower's neighborhood. The agent moving by eq-(5) is called a follower because it follows a predecessor.

If an agent is not updated by (4) or (5), it moves by

$$P(k, t+1) = \text{Rd}\{\alpha(k, t; i) \mid (j \in K') P(j, t) \neq \alpha(k, t; i) \wedge \alpha(k, t; i) \notin U_N\} \quad (6)$$

where  $K'$  is an index set of agents that are not updated. An agent moving by eq-(6) is called a free mover.

Finally, principal vectors are locally matched with each other in the neighborhood through velocity matching,  $M$ . This matching operation is expressed as

$$\theta_{k,t+1} = \langle \theta_{k,t} \rangle_M. \quad (7)$$

The bracket with  $M$  represents the operation of averaging velocity directions in the neighborhood,  $M$ .

Fig. 1a shows the neighborhood of velocity matching and of the follower. Figure 1b shows the procedure of velocity matching, mutual anticipation, and following.

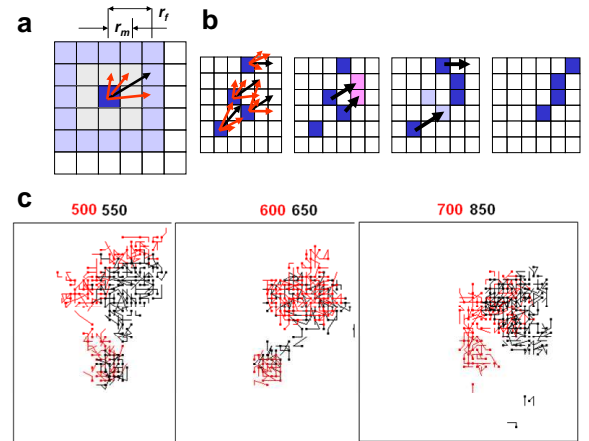

Figure 1 Schematic diagram of the transition and time development of the model simulation: (a) Principal vector (black arrow) and alternative vectors (red arrows) of a crab (blue square) in the matching neighborhood with radii  $r_m$  (pale gray lattices) and the following neighborhood with radii  $r_f$  (pale gray + pale blue lattices). (b) Transitions of crabs in a two-dimensional discrete space. Velocity matching (far left), mutual anticipation (second from left), following and free movement (second from right) and the resulting distribution at the next step (far right). (c) Time development ( $t = 500-850$ ) of our swarm model of 100 agents, with  $P = 20$ ,  $\alpha = 0.9$ ,  $L = 4$ ,  $r_a = r_f = 2$ .

First, velocity matching is applied to the principal vectors, and the agents then move to the most popular site (pink site in Fig. 1b), yielding a vacant site (pale blue site in Fig. 1b). Highly popular anticipated sites propagate backward in time, revealing the asynchronous transitions. Thus, mutual anticipation is here implemented by back propagation in time. Agents move to a vacant site if it is within the follower's neighborhood. Fig. 1c shows a series of snapshots of our swarm model. Each agent is represented with its 5-step trajectories. It is easy to see that a swarm contains turbulent motion despite maintaining a highly dense whole.

Fig. 2a shows polarization/density of a swarm plotted against external perturbation in our model with  $P = 1$ . Polarization is defined by the length of the average velocity over all agents in a swarm. Density is defined by the average number of agents in the neighborhood of  $20 \times 20$  lattices. In the model with  $P = 1$ , the external perturbation,  $\xi$ , is randomly chosen from  $[0, 1]$  and is coupled with velocity matching. When the projected velocity of agent is expressed as  $(v_x, v_y)$ ,  $v_x + \xi$  and  $v_y + \xi$  are given for the unit vector. If  $P = 1$ , the model corresponds to BOIDS because each agent has only one velocity. The coherence of a swarm can result only from velocity matching or high polarization; the more polarized and dense the population, the less external perturbation there is.

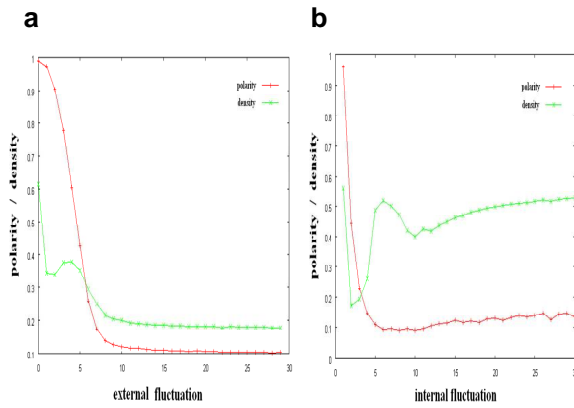

Figure 2 Polarization/density plotted against perturbation. (a) The polarization/density ratio plotted against external perturbation in the model with  $P = 1$ . (b) The ratio plotted against internal perturbation, which is defined as the number of potential transitions normalized by the maximum number of potential transitions. For this plot,  $P$  ranged from 1 to 30.

Fig. 2b shows the polarization/density of a swarm plotted against the inherent perturbation in our model. The inherent perturbation is expressed by  $(P - 1)/P_{\text{MAX}}$ , where  $P$  is given from 1 to  $P_{\text{MAX}}$  (30). The more inherent noise (i.e., more  $P$ ) that is present, the higher the density and the lower the polarization are. This relationship reveals that a highly dense swarm is generated by mutual anticipation and/or inherent noise. For this reason, a coherent swarm (i.e., a highly dense swarm with an extrinsic boundary) contains inherent turbulence.

In the next section, we illustrate how inherent noise positively contributes to robust swarm behavior by demonstrating the role of noise in water-crossing behavior, hour glass behavior and collision-based computing implemented by swarm balls.

### Water-crossing behavior

The water-crossing behavior observed in real soldier crabs can be easily approximated by our model. To introduce a tidal pool into the simulation, we define a specific area  $U_p \subseteq S \times S$  in which the condition allowing mutual anticipation is replaced by

$$\zeta(\alpha(k, t; i)) \geq c. \quad (8)$$

The value  $c$  is an integer larger than 2. Because  $c > 2$ , it is more difficult for agents to go through the area  $U_p$ . Only by introducing the specific area  $U_p$  can we simulate the behavior of crossing water.

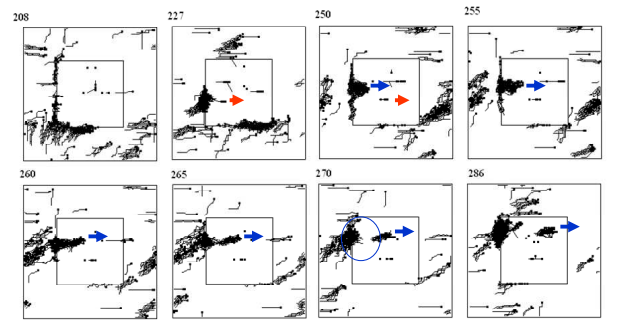

Figure 3 Snapshots of the time development of swarm trajectories in a model simulation. Numbers in the upper left of each plot denote the time step. Each agent is represented with its 5-step trajectories. The rectangle located in the center indicates  $U_p$ , which represents a tidal pool. For these simulations,  $P = 10$ ,  $\alpha = 0.3$ ,  $L = 4$ , and  $r_a = r_f = 2$ . Blue and red arrows represent the directions of motion of swarms. Blue circle represents highly concentrated area of a swarm.

Fig. 3 shows a series of snapshots of our swarm model demonstrating water-crossing behavior. Although a single agent or a small swarm cannot enter the tidal pool, a highly concentrated, large swarm can enter and cross the tidal pool. These behaviors are consistent with the behaviors of real soldier crabs observed in Iriomote islands.

Fig. 4 shows the frequency of a swarm invading the tidal pool in a model given by  $P = 20$ ,  $\alpha = 0.5$ ,  $L = 4$ , and  $r_a = r_f = 2$ . For each experiment, we prepared 2000 cases of a swarm confronting the tidal pool. If the size of a swarm exceeds a certain value, a constant high probability of invasion is achieved. If  $P$  is smaller, the possibility of which the popularity exceeds the threshold decreases. Thus, the minimum size of a swarm invading the tidal pool increases.

Because a swarm generated by our model is so robust that a swarm can go through the tidal pool once the swarm enters

the water. Yet, if an agent is isolated in the water, then he or she cannot move and is left alone. This phenomenon is also observed in real soldier crabs.

Figure 4 Frequency of a swarm invading a tidal pool as a function of swarm size.

### Hourglass made of soldier crabs

In field observations, we found a soldier crab moving along the wall in a closed container, and we created an hourglass made of real soldier crabs (Nishiyama et al., 2011). Forty soldier crabs are collected and are confronted in a closed container, where the floor was made of cork providing friction enough to walk for soldier crabs. If the container is left for while, soldier crabs walk along the wall in keeping a half-broken swarm. Since a concentrated swarm oscillates along the wall, the hourglass made of soldier crabs produced periodic oscillations for approximately two or three hours with a period of 70 seconds.

This behavior can be approximated by our model by slightly modifying one rule.

To simulate hourglass behavior as shown in Fig. 5 and 6, we introduced a tendency to walk along a wall. The hourglass scenario is constructed as follows. We first defined the wall state for any lattice  $(x, y)$  such that

$$w(x, y) = 1 \text{ if the site is the wall state;} \quad (9)$$

$$0, \text{ otherwise.}$$

In the hourglass simulation, an agent can be located only at a site where  $w(x, y) = 0$ . The angle of tangential direction is defined for each wall state site  $(x, y)$  and is represented by  $\theta_w(x, y)$ . The tendency of walking along a wall is defined by

$$\theta_{k,t} = R d\{\beta, \beta + \pi\} \quad (10)$$

$$\beta = R d\{\theta_w(x, y) | d(\mathbf{P}(k, t), (x, y)) \leq d(\mathbf{P}(k, t), (u, v)), w(x, y) = w(u, v) = 1, (x, y), (u, v) \in N_w\}, \quad (11)$$

where  $d((p, q), (x, y))$  represents the metric distance between two sites  $(p, q)$  and  $(x, y)$ , and  $N_w$  represents the neighborhood of wall-monitoring for each agent. If an agent is close to the wall with respect to  $N_w$ , the agent's velocity,  $\theta_{k,t}$  is parallel to

the tangential direction of the wall. After this operation, velocity matching (equation (7)) is applied to all agents. Only from (10) and (11) can agents close to the wall walk along the wall and other agents pass using the shortcut.

Figure 5 Snapshots of the time development of swarm move in the model simulation for the hourglass. Time proceeds from left to right and top to bottom. For this simulation,  $P = 10$ ,  $\alpha = 0.5$ ,  $L = 4$ , and  $r_a = r_f = 2$ . Each agent is represented by a black square with its own trajectory. First (top left) a main swarm is located at right hand, and then it moves to the left (top right). After that the swarm moves to the right again (middle center), and so on.

A solitary agent separated from a flockmate in our model undergoes a random walk because a potential transition is randomly chosen for each step. It follows that potential transitions stand for inherent noise. Whenever agents are highly concentrated, mutual anticipation can occur; inherent noise positively contributes to form a dense swarm. Thus, even if agents are exposed to large external perturbations, the perturbed transitions cannot be distinguished from inherent noise. A swarm resulting from mutual anticipation is thereby robust to external perturbation. In order to demonstrate the robustness of a swarm we implement “crab hour glass” (Nishiyama et al., 2011).

Fig. 5 shows snapshots of model simulations. It was assumed that an individual has a principal vector parallel to the tangent of the wall if it was close to the wall, in which the direction is chosen with uniform probability to be clockwise or anti-clockwise. Other rule settings were the same as in previous models. In the simulations, high concentrations initially occurred at the left or right ends, and the swarm rotated anti-clockwise. Most of the individuals walked along the wall, and some followed shortcuts. After a long period, the rotational direction reversed from clockwise to anti-clockwise and vice-versa.

The numbers of individuals in the divided areas (left, center, and right) shows regular oscillations (Fig. 6). The oscillating behavior of the model satisfies the properties of an hourglass of real soldier crabs. This oscillation mechanism is different from the periodic pattern of insect swarms based on escape-and-pursuit behavior.

Figure 6 Numbers of agents in the left (blue), center (red) and right (green) areas of the container over time. For this simulation,  $P = 10$ ,  $\alpha = 0.5$ ,  $L = 4$ , and  $r_a = r_f = 2$ .

### Logic gates made of soldier crabs

A swarm is so robust that it can be used as a ball for collision-computing (Adamatzky, 2002). In addition to the hourglass model, we prepared a special scenario in which the area in which agents can move freely is tightly bounded by a wall, and there is a gradient of preferred direction. The constructed OR gate made of agents is shown in Fig. 7.

Each diagram of Fig. 7 shows a snapshot of the behavior of OR gate in time. Two entrances on the left represent input positions for two variables  $x$  and  $y$ , and one exit on the right represents the output position for  $x \text{ OR } y$ . If a swarm is present at position  $x$ , this state represents  $x=1$ . Agents move along the wall and rightward because of the gradient. After the collision of two swarms (each consists of 40 agents), the united swarm moves rightward and reaches the output position. It reveals  $x \text{ OR } y = 1$  for  $(x, y) = (1, 1)$ . Because  $x \text{ OR } y = 1$  for  $(x, y) = (0, 1)$  or  $(1, 0)$ , and  $x \text{ OR } y = 0$  for  $(x, y) = (0, 0)$ , this setup can implement the OR gate.

Figure 7 An OR gate of swarm balls. A swarm ball consists of 40 agents. Each agent is represented by a square with its 5-step trajectories. Four snapshots of a swarm at different time steps are

numbered. Red arrows represent the direction of motion of a swarm ball.

AND and NOT gates were also constructed using a swarm. Fig. 8 shows the behavior of an AND gate. In each diagram, two entrances on the left represent  $x$  and  $y$  for input, and the three exits on the right represent  $x \text{ AND } \text{NOT}(y)$ ,  $x \text{ AND } y$ , and  $\text{NOT}(x) \text{ AND } y$ , respectively. In the central exit on the right, there is a tidal pool in which a small swarm cannot enter. We define the tidal pool as a specific area  $U_p$  with the threshold  $c = 10$ . Because a swarm of 40 agents at the input position cannot enter the tidal pool, it retreats after the contact with the tidal pool and moves toward the output of  $x \text{ AND } \text{NOT}(y)$ .

Figure 8 An AND gate of swarm balls. A swarm ball consists of 40 agents. Each agent is represented by a square with its 5-step trajectories. Four snapshots of a swarm at different time steps are numbered. Red arrows represent the direction of motion of a swarm ball.

Figure 9 An AND gate of swarm balls. A swarm ball consists of 40 agents. Each agent is represented by a square with its 5-step trajectories. Four snapshots of a swarm at different time steps are numbered. Red arrows represent the direction of motion of a swarm ball.

Fig. 9 shows the behavior of an AND gate for  $(x, y) = (1, 1)$ . In this case, the collision of two swarms creates a large and united swarm, which enters the tidal pool. Thus, a united swarm produces the output of  $x$  AND  $y$ . If a swarm ball located at the input position of  $y$  is part of the logic gate,  $\text{NOT}(x)$  AND  $y$  can be utilized for  $\text{NOT}(x)$  for input  $x$ . Thus, this device can be utilized as a NOT gate. In this AND gate for  $(x, y) = (1, 1)$  sometimes the united swarm does not enter the water pool. It results in low performance (72%).

Figure 10 Another AND gate of swarm balls. A swarm ball consists of 40 agents. Each agent is represented by a square with its 5-step trajectories. Four snapshots of a swarm at different time steps are numbered. Red arrows represent the direction of motion of a swarm ball.

Thus we construct another AND gate as shown in Fig. 10. We set the initial principal directions of agents by the direction along the corridor represented by red arrows in the diagram 1 in Fig. 10. Actually we implement this gate by real soldier crabs. If the soldier crabs are set at the initial position and are threatened by a shadow suddenly appeared, they move straight. That is underlying implementation corresponding to the initial setting for principal vectors of agents. The swarms go straight. After the collision the united swarm moves following the united vectors. The performance of this AND gate is beyond 95%.

We here show three dynamics of our swarm model, water-crossing, hourglass and logic gate behaviors. The underlying mechanisms are based on mutual anticipation or inherent noise, which contribute to a robust, coherent swarm containing inherent turbulence. The characteristic flexibility and robustness of a swarm can be compared to a human's body awareness. A bird flock forms a large sub-domain that scales linearly with flock size. Because the proportion of the correlated domain against flock (body) size is constant, the flock appears to move as a single body (Cavagna et al., 2010). Our model can also show the scale-free correlation that has been observed in starlings and soldier crabs (Murakami et al., 2011). We believe that mutual anticipation is a key component in the generation and/or embedding of body awareness in a system. We now implement these logical gates by real soldier crabs, and the results will be given anywhere.

Robustness of a swarm plays an essential role in water-crossing, hourglass and logic gate behaviors. Because of robustness, a swarm can cross the water without being fallen into separated, hour glass shows periodic oscillation and logic gate shows high performance. In our model inherent noise (i.e. a number of potential transitions for each agent) contributes to make a robust swarm. Even if external perturbation is very large, the inherent noise cannot be distinguished from external perturbation. It entails that even external noise can coordinate to a robust swarm.

Even if the external noise increases, density and polarization of a swarm is not changed at all and a robust swarm is maintained, as shown in Fig. 11. The external perturbation is given by the product of the strength of a noise,  $\lambda$  and random variable,  $\xi$ . The random variable,  $\xi$ , is randomly chosen from  $[0, 1]$  and is coupled with velocity matching. When the projected velocity of agent is expressed as  $(v_x, v_y)$ ,  $v_x + \lambda\xi$  and  $v_y + \lambda\xi$  are given for the unit vector. In this simulation  $P = 20$ ,  $\alpha = 0.5$ ,  $L = 4$ , and  $r_a = r_f = 2$ . We tried other conditions with respect to  $P$ , and obtain similar results of polarization and density for  $10 < P < 20$ .

Figure 11. Polarization and density of a swarm generated by the model plotted against external noise.

In the next section, we discuss the significance of mutual anticipation to embodiment.

### Future and Past coordinate Present

The question whether a swarm, flock or school has a single consciousness or body has been addressed by investigating kinetic data from real animal groups and model simulations. A notable finding is that a swarm or a flock has a scale-free proportion of correlated domains, which reveals embodied collective behavior. Although it has been suggested that the interplay between anticipated states and memory states can contribute to a scale-free correlation in an asynchronous updating model (Gunji et al., 2011), our model is the first attempt to implement the interplay of anticipated and memory states in a swarm. We here discuss the relationships among the concept of body awareness, the interplay of anticipated and memory states, and flexibility and robustness.

Body awareness is studied in terms of a sense of ownership (SoO) and of a sense of agency (SoA) in neuroscience. It is known that SoO and/or SoA can be easily implanted in an object instead of a participant's own body through a synchronous interplay of visual and tactile stimuli (Ramachandran et al., 1996, 1998).

The generation of SoO and SoA in cognitive systems has also been studied. Fig. 10a shows a schematic diagram of SoO and SoA in sensory-motor coupling (Pfeifer, et al., 2007, Gallagher, 2000, Synofzik, 2008). After receiving a stimulus from the environment, a controller (brain) computes the anticipated state of its motor to adapt itself to the environment. The order from the controller is sent to the motor, and the actual state is revealed. A reaction from the environment is received again. In this scheme, the anticipated state processed on motor command is compared to the original intention in a controller. Because the comparison between the anticipated state and the original intention is executed before the motor moves, it constitutes a feed-forward process. In contrast, the actual state of the motor is compared to the original intention after the movement of the motor. This dynamic constitutes a feed-back process. SoA is thought to be related to a feed-forward and SoO to a feed-back process (Gallagher, 2000).

Figure 12. Sense of ownership (SoO) and sense of agency (SoA) in embodiment compared with body awareness in a swarm model. (a) Schematic diagram of SoO and SoA in a sensory-motor coupling system. (b) The schematic diagram of SoO and SoA in a system in which the sensory-motor distinction is vague in the “embodied body”. (c) SoA and SoO in our swarm model. Blue arrows represent back propagation in time from the anticipated popularity of transitions.

Because adaptive cooperation in a system entails the exploitation of decentralization and embodiment, the body includes redundancy resulting from reciprocal conflicts among components (Cruse et al., 2006). Such redundancy makes it possible to achieve complementary interplay between different modalities without forced learning and can result in a vague distinction between body and environment (Lungarella et al., 2006). The body and/or the boundary between the body and the environment is perpetually generated and maintained. The scheme involving SoO and SoA when the environment,

sensor and controller are mixed up in the form of body is represented in Fig. 12b. The motor command and motor are here represented by their featured, anticipated and memory states. In Fig. 12a, SoO and SoA constitute a hierarchical system. However, if there many redundant paths from controller to motor and embodiment between parts of the system can occur (i.e. the boundary of subsystems in a sensory-motor system becomes indefinite), the relationship between SoO and SoA in Fig. 12a can be replaced by that in Fig. 12b in which SoO and SoA are distributed in a parallel manner (Gunji, Sonoda & Niizato, 2011). The connection between SoO and SoA is dynamically generated to ensure consistency.

The dynamical connection between SoA and SoO is embedded in our swarm model. Through mutual anticipation, the anticipated popular sites are propagated backward in time, which can reveal actual transitions by asynchronous updating. Due to asynchronous updating and the avoidance of collisions by agents, a swarm is perpetually generated as a coherent system. These features can give rise to dynamic, flexible and robust swarming. After that, actual transition is memorized and is utilized as a principal vector to generate inherent noise (i.e., potential transitions) along the principal vector. SoO is here implemented as a reservoir to generate inherent noise or potentiality.

The underlying mechanisms of SoO and SoA emerge clearly in our swarm model. The interplay of anticipation and memory plays a central role in flexible and robust swarming. This interplay is characteristic of body awareness. Because a swarm is generated as a “body”, it can show a coherent density containing inherent turbulence. The swarm is robust to perturbed environments. A system that appears to be in equilibrium (e.g., a swarm ball or hourglass showing periodic oscillations) is in fact perpetually and robustly generated far from equilibrium. The idea of a “body” is thus well-defined not in the context of stability but of robustness.

## Conclusion

Based on the field observations of soldier crabs, *Mictyris guinotae*, we find that inherent noise can contribute to a dynamic and coherent swarm in which internal turbulence continuously flows. We implement such a phenomenon by an aggregation of agents of which each one have multiple potential transitions and can anticipate with each other. As a result we obtain dynamic and robust swarm even against the external perturbation.

Due to the robustness the swarm cannot be disturbed in perturbed environments such as water pool, and can be utilized as hour glass and logic gate. They are preliminary implemented by real soldier crabs, and that can be approximated by our model.

Since the swarm model is equipped with anticipation and memory, the model can be compared to the comparator model for SoA and SoO in body image, as long as a hierarchical structure is given up. Two loops including anticipated state or past state (memory) can cooperated with generating the current state. This structure is an essential structure to generate human body image. Our argument entails that a

swarm structure in our model can have a similar structure. Actually in the swarm a part of the swarm can be moved and operated by the swarm itself (corresponding to SoA). It results in a coherent and robust swarm as a whole not to be fallen into collapse of the swarm. This is the first step to connect the swarm with body image with respect to inherent time structure.

## Abstract

A grand challenge in the field of artificial life is to find a general theory of emergent self-organizing systems. In this paper we try to explain the emergent behavior of a simulated swarm by applying methods based on the fluctuation theorem. Empirical results indicate that the swarm is able to produce negative entropy within an isolated sub-system due to ‘frozen accidents’. Individuals of the swarm are able to locally detect fluctuations of the global entropy measure and store them, if they are negative entropy productions. By accumulating these stored fluctuations over time the swarm as a whole is producing negative entropy and the system ends up in an ordered state. We claim that this indicates the existence of an inverted fluctuation theorem for emergent self-organizing dissipative systems. This approach bears the potential of general applicability.

## Introduction

One characteristic of living organisms is their metabolism. Living beings require energy in order to maintain their internal order. This is determined by the second law of thermodynamics that describes the ubiquitous decay of all things and does not allow the increase of order without the cost of dissipation. In the context of self-organizing systems one might cite Parunak and Brueckner (2001): “Emergent self-organization in multi-agent systems appears to contradict the second law of thermodynamics.” This is of course not the case, as discussed by Parunak and Brueckner (2001), one has to distinguish between two kinds of sub-systems: one that hosts the self-organizing swarm and one in which disorder is increased. Hence, a swarm can be thought of as a heat pump that decreases entropy<sup>1</sup> in one basin in favor of increased entropy in another basin. However, the question of how the swarm manages to do that still persists. Whether thermodynamic properties are relevant and helpful in understanding such systems is currently discussed (Polani, 2008; Hamann et al., 2011a).

<sup>1</sup>In principle, we refer here to Gibbs entropy  $S = -k_B \sum_i p_i \ln p_i$ , for Boltzmann constant  $k_B$  and the sum over all microstates with probabilities  $p_i$  which applies especially to classical, finite systems far away from equilibrium. However, an intuitive understanding of entropy suffices in the following.

The emergence of life is explained by natural selection in combination with random events (natural evolution). It is one thing to select the adapted organism but the mutation, that results in an improved adaptivity, has to occur first. Concerning the genetic code Crick (1968) phrased the term ‘Frozen Accident Theory’. While Crick was introducing this concept with focus on genetics, Gell-Mann (1995) applied it to everything:

[...] the effective complexity [of the universe] receives only a small contribution from the fundamental laws. The rest comes from the numerous regularities resulting from ‘frozen accidents’.

The intuition of this theory is relatively clear in the context of the slow evolution of our universe. However, we want to define a concept of frozen accidents within emergent self-organizing multi-agent systems (De Wolf and Holvoet, 2005) that explains how they can work as heat pumps in the sense as described above.

While a heat pump has to work against the second law (e.g., diffusion of heat) by expending energy, limited violations of the second law without the expenditure of energy (Evans et al., 1993) are also possible as, for example, indicated by Maxwell (1878):

The truth of the second law is ... a statistical, not a mathematical, ... for it depends on the fact that the bodies we deal with consist of millions of molecules.

Violations of the second law are possible for small systems and short time scales, that is, at atomic and micron scales over short times (up to two seconds), and were shown experimentally (Wang et al., 2002). We claim that the reduction of entropy by emergent self-organizing systems could be explained by the ‘summation’ of such violations to the second law. The second law is only statistical and, hence, allows spontaneous decreases of entropy in isolated systems with nonzero probability.

The possibility of temporal entropy decreases exists because a system at a temperature above absolute zero according to statistical mechanics always shows thermal fluctuations, that

are random deviations of a system from its equilibrium. Say  $x$  is a thermodynamic variable (i.e., it describes a state of a thermodynamic system at a given time) then the probability distribution  $f(x)$  of this variable for a system at maximum entropy (at equilibrium state) turns out to be Gaussian with mean  $\mu = 0$ :

$$f(x) = \frac{1}{\sqrt{2\pi\langle x^2 \rangle}} \exp\left(-\frac{x^2}{2\langle x^2 \rangle}\right), \quad (1)$$

for the variance defined by the mean square fluctuation  $\sigma^2 = \langle x^2 \rangle$ , which is an average over many ensembles (i.e., average over many realizations of the system). Hence, the probability of observing negative ( $\int_{-\infty}^0 f(x)dx$ ) or positive fluctuations ( $\int_0^{+\infty} f(x)dx$ ) is equal at equilibrium.

The fluctuation theorem (Evans and Searles, 2002; Evans et al., 1993) quantifies the probability of violations to the second law. For short intervals it can be said that nature was running in reverse. Even concerning living systems this might be true. For example, small ‘machines’ within a cell (e.g., mitochondria) are likely to run in reverse from time to time. A transfer of this concept to the macro-world is typically denied categorically. In a review of Wang et al. (2002), Gerstner (2002) wrote: “For larger systems over normal periods of time, however, the second law of thermodynamics is absolutely rock solid.”

Generally the fluctuation theorem is said to be applicable only to the micro-world, where Brownian motion can be observed. Truly, this is a well chosen hypothesis. However, what if we allow dissipation of energy in the first place, separate the system in two sub-systems of the self-organizing part and a heat bath, and then observe only the behavior in the self-organizing half of the system? That way one could argue that we simulate the micro-world by a macro-system at the cost of lost heat. This concept (see Fig. 1) is for example taken into account by Smith (2008) when stating

$$dQ = -k_B T dS \equiv k_B T d\mathcal{I}, \quad (2)$$

for an increment of heat  $dQ$  rejected by the system to a thermal bath at temperature  $T$ , Boltzmann constant  $k_B$ , reduction in entropy of the (sub-)system’s internal state  $-dS$ , and the increase in information  $d\mathcal{I}$  (note that Smith (2008) defines information as “the reduction in some measure of entropy”). Note that the mere property of being dissipative is not sufficient to explain a self-organizing system. In addition to squandering energy the system has to generate orderly structures. Dissipation is only a necessary condition for negative entropy production while additional sufficient conditions exist. In case of Rayleigh-Bénard convection (Bodenschatz et al., 2000), for example, initially fluctuating flows (Wu et al., 1995) occur that are enhanced and trigger the formation of Bénard cells in spontaneous symmetry breaking, cf. also (Nicolis and Prigogine, 1977; Haken,

Figure 1: Schematic of a system divided into a heat bath with increasing entropy and a self-organizing, dissipative sub-system with decreasing entropy.

1977). We want to point out the self-amplification of fluctuations as such a sufficient condition here.

In this paper, we report empirical evidence that the negative entropy production in emergent self-organizing systems is based initially on frozen accidents allowed by the original fluctuation theorem which, in turn, leads in the end to a global behavior that is described by an inversion of the fluctuation theorem in dissipative self-organizing systems. This concept might bear potential of embedding the concept of emergent behavior in multi-agent systems (swarms, self-propelled particles etc.) in a theoretical framework built on sound foundations of theories from physics. Hence, we propose an approach to understand emergent behavior through thermodynamics which follows up our earlier reported concept (Hamann et al., 2011a).

In addition, the relation to the fluctuation theorem might allow to define preconditions for effective self-organizing systems in the future. For example, one can define minimum requirements for the agents of the system concerning its cognition abilities in order to be able to leverage fluctuations. The agent needs sensors that allow to estimate at least probabilistically whether the (local) entropy has just decreased. Furthermore, the system needs the ability to store such local fluctuations.

In the following we describe the investigated scenario and the fluctuation theorem. We analyze the multi-agent system or swarm, discuss how the results could be viewed as obeying an inverted fluctuation theorem and conclude by giving a short summary and outlook.

## BEECLUST algorithm

The BEECLUST algorithm can be considered a model algorithm for swarms. It is based on observations of young honeybees (Szopek et al., 2008), was analyzed in many models (Hereford, 2011; Schmickl and Hamann, 2011; Schmickl et al., 2009; Hamann et al., 2011b, 2010), and even implemented in a swarm of robots (Schmickl et al., 2008).

This algorithm allows a swarm to aggregate at a maximum of a gradient field although individual agents do not perform a greedy gradient ascent. Hence, it might be justified to

Figure 2: Bottom: Typical state of a swarm controlled by BEECLUST; positions of stopped agents (circles) and moving agents (triangles) with trajectories of the last 20 time steps, contours show levels of the gradient field. Top: function used in eq. 7.

- 1.) Each agent moves straight until it perceives an obstacle  $O$  within sensor range.
- 2.) If  $O$  is a wall the agent turns away and continues with step 1.
- 3.) If  $O$  is another agent and there is a third agent as well, the agent measures the local gradient value. The higher the gradient value the longer the agent stays still. After this waiting period, the agent turns away from the other agent and continues with step 1.

Figure 3: The BEECLUST algorithm (stop threshold of 3).

call this emergent behavior. Controlled by this algorithm three agents will stop (note that in previous works typically a threshold of two was chosen, which is, however, irrelevant in this paper) when they approach each other, measure the local value of the gradient, and wait for some time proportional to this measurement. Clusters form and finally the swarm will be aggregated close to the global optimum of the gradient field (see the lower part of Fig. 2). See Fig. 3 for a definition of the BEECLUST algorithm.

The collective aggregation close to the global optimum is achieved via a positive feedback process (Hamann et al., 2011b): Clusters of 3 stopped agents will form by chance anywhere in the arena. Agents in clusters closer to the global optimum have longer waiting times. These clusters will exist longer than those that are farther away from the global opti-

Table 1: Used parameter setting in this work.

arena dimensions	$150 \times 50$ [length units] <sup>2</sup>
proximity sensor range	3.5[length units]
max. waiting time	660[time units]
velocity	3[length units]/[time units]
number of agents	25

mum. Hence, the chance of growing into a cluster of size 4 is bigger for clusters closer to the global optimum. The area covered by clusters grows with the number of contained agents and clusters covering a bigger area are more likely to be approached by chance by moving agents. Hence, bigger clusters will grow faster. This process, typically, leads to just one big cluster close to the global optimum. The agents interact only locally and a BEECLUST-controlled swarm is able to break symmetries (Hamann et al., 2011b). Hence, this behavior is different from other aggregation processes, for example, star formation which includes global interactions due to gravitation.

In the following experiments, the agents have initially random headings, are in the state ‘moving’, and are random uniformly distributed in the arena. The gradient field is bimodal with maxima of the same value and shape (see contours in Fig. 2). See Table 1 for the standard parameters used.

## Fluctuation Theorem

According to Evans and Searles (2002) the group of fluctuation theorems “gives an analytical expression for the probability of observing Second Law violating dynamical fluctuations in thermostatted dissipative non-equilibrium systems.” In a thermostatted system the temperature is kept constant, for example, by rescaling the particles’ velocities. The system can be thought of as being in contact with a large heat reservoir in order to thermostat the system. One of these theorems (steady state fluctuation theorems) applies to time-reversible, thermostatted, ergodic dynamical systems and defines the relation of fluctuations (Evans and Searles, 2002)

$$\lim_{t \rightarrow \infty} \frac{1}{t} \ln \frac{P[\bar{\Sigma}_t = A]}{P[\bar{\Sigma}_t = -A]} = A, \quad (3)$$

for the time averaged entropy production  $\bar{\Sigma}_t = (1/t) \int_0^t \Sigma(s) ds$ . The fluctuation theorem compares probabilities of observing a certain time averaged entropy production  $A$  to its negative value  $-A$ . The value  $P(\bar{\Sigma}_t = A)$  describes the probability of finding the system initially in those states that subsequently generate bundles of trajectory segments with the time averaged value  $A$ . The above theorem (eq. 3) predicts an exponential increase of the relation  $P(\bar{\Sigma}_t = A)/P(\bar{\Sigma}_t = -A)$ . Hence, with increasing time positive entropy producing trajectories become exponentially more likely than their negative entropy producing counterparts.

As a consequence of the fluctuation theorem one obtains the Second Law Inequality

$$\langle \bar{\Sigma}_t \rangle \geq 0, \quad \forall t, \quad (4)$$

which states that the average over many ensembles, in which the time averaged entropy productions were measured, is positive. Hence, the fluctuation theorem is in accordance with the second law of thermodynamics.

### Analysis of BEECLUST

We consider a system of  $N$  agents that move in a two-dimensional box and gradient field. We assume the particles to move frictionless which basically means they have a permanent acceleration compensating friction. This, in turn, means they have an energy reservoir (cf. active particles (Schweitzer, 2003)) and permanently dissipate heat which results in a situation as shown in Fig. 1. In addition, we allow infinite accelerations because the agents stop and start within one time step in our numerical simulation. Energy costs have to be paid to allow self-organization and to comply with the second law of thermodynamics. In the following we carry out the separation between these two sub-systems: the self-organizing sub-system containing the agents and the sub-system typified by the heat reservoir. Due to its energy dissipation the self-organizing sub-system does not have to obey the second law of thermodynamics. We define the following equations of motion for each agent  $i$

$$\dot{\mathbf{q}}_i = \mathbf{p}_i/m, \quad (5)$$

$$\dot{\mathbf{p}}_i = \mathbf{F}_i + \begin{cases} -\mathbf{p}_i, & \text{particle autonomously stops} \\ \mathbf{p}'_i, & \text{particle autonomously starts} \\ 0, & \text{else} \end{cases}, \quad (6)$$

where  $\mathbf{q}_i = (x_i, y_i)^\top$  is the position of agent  $i$ ,  $\mathbf{p}_i$  is the momentum, and  $\mathbf{p}'_i$  is the value of  $\mathbf{p}_i$  at the time the agent had stopped. We have  $\mathbf{F}_i > 0$  in case the agent bounces off the bounds or closely approaches another agent. This can be implemented, for example, via a WCA potential (Weeks et al., 1971), which is a purely repulsive potential. As thermostat method we use velocity scaling which is governed by the number of stopped agents. In particular, the special periods of time in which all agents are stopped are converted to time periods of no extend. Note that this is only our method of measuring the self-organizing system. It is not intrinsic to the system and the behavior of the agents is unconcerned by this method.

The system dynamics takes place in a high dimensional phase space  $(\mathbf{q}_0, \mathbf{q}_1, \dots, \mathbf{q}_{N-1}, \mathbf{p}_0, \mathbf{p}_1, \dots, \mathbf{p}_{N-1}) \in \Gamma$ . In the following we need to detect the essentials of this dynamics by a measure of entropy. We ignore the momenta  $\mathbf{p}$  and also the y-positions because the main feature of the clusters is defined by the agents' x-positions (see Fig. 2). Ignoring

Figure 4: Distribution of the entropy production for a swarm controlled by the BEECLUST algorithm,  $t = 1500$ ,  $\langle t\Omega \rangle \approx 15.77$ ,  $T = 909.1$ , number of samples  $n \approx 5.0 \times 10^6$ .

the momenta does not hide entropy. Although we start with all nonzero momenta and during the experiments we have inhomogeneous momentum distributions but the experiments typically end with almost all agents stopped (i.e., again a homogeneous momentum distribution). Similar to (Evans and Searles, 2002, Sec. 4.3) we observe the agent density modulation via

$$\rho(k, t) = \sum_{i=1}^N \sin(kx_i(t) + \frac{\pi}{2}), \quad (7)$$

where  $x_i(t)$  is the x-position of agent  $i$  at time  $t$ ,  $k = 2\pi/L$ , and  $L = 150$  is the box length. The applied sine-function is shown in Fig. 2. Agents in the leftmost and rightmost quarters of the arena contribute positively, agents in the middle contribute negatively. In equilibrium,  $x_i \in [0, L]$  would be equally distributed averaged over many ensembles, yielding  $\langle \rho \rangle = 0$ . By applying the converse argument, averages of  $\langle \rho \rangle \neq 0$  would correspond to unequal distributions of agents whereas negative and positive values indicate whether the main cluster is in the middle or at the ends.

Following Evans and Searles (2002) we define a ‘dissipation function’  $\Omega(\Gamma)$  that gives the entropy production for a given phase space trajectory. We integrate changes of  $\rho$  over a time interval  $[0, t]$

$$t\Omega = \beta \int_0^t \dot{\rho}(k, s) ds = \beta(\rho(k, t) - \rho(k, 0)) \quad (8)$$

and

$$\beta = 1/T = \left( \frac{2}{k_B N_d} \left\langle \sum_{i \in [0, N-1]} \frac{\mathbf{p}_i^2}{2m} \right\rangle \right)^{-1} \quad (9)$$

is the reciprocal temperature of the initial ensemble with Boltzmann constant  $k_B$  and degrees of freedom  $N_d = 2N$ . The distribution of the entropy production for  $N = 25$  agents controlled by the BEECLUST algorithm, which were

Figure 5: Test of the entropy production distribution of the BEECLUST-controlled swarm shown in Fig. 4 against the fluctuation theorem (eq. 10),  $Y = \frac{1}{\beta t} \ln \frac{P[\rho(k,t) - \rho(k,0) = A]}{P[\rho(k,t) - \rho(k,0) = -A]}$ ,  $t = 1500$ ,  $T = 909.1$ . Note that any  $Y \neq 0$  corresponds to negative entropy production.

initially random uniformly distributed, is shown in Fig. 4 for  $t = 1500$ . The initial uniform distribution yields  $\langle \rho(0) \rangle = 0$  which is the state of maximal entropy. Hence, any distribution of the entropy production with a mean of  $\langle t\Omega \rangle \neq 0$  indicates negative entropy production (i.e., averaged differences of the density modulation can have negative or positive signs but imply negative entropy production, if they are nonzero). The ensemble average is  $\langle t\Omega \rangle \approx 15.77$  which means that negative entropy is produced (initially at maximum entropy). Note that there is no direct influence by the gradient field to the entropy productions which are defined based on the agents' x-positions. Furthermore, the waiting times, that are determined by the gradient field, vary only by a factor of 5 between the minimum and the maximum. Now we want to apply the fluctuation theorem (eq. 3) to this system. Especially we have to assume time-reversibility which is problematic because BEECLUST-controlled systems are in general not reversible (Hamann et al., 2011a). However, we argue that it is fair to assume approximate reversibility because the irreversibility vanishes, if the agents measure almost equal gradient values (typically the difference is only about  $\pm 10\%$ ) determining almost equal waiting times and almost equal wake-ups. Applying the fluctuation theorem gives

$$\lim_{t \rightarrow \infty} \frac{1}{t} \ln \frac{P[\rho(k,t) - \rho(k,0) = A]}{P[\rho(k,t) - \rho(k,0) = -A]} = \beta A. \quad (10)$$

The data shown in Fig. 4 is tested whether it obeys eq. 10 in Fig. 5. The fluctuation theorem is satisfied for this system although the system is producing negative entropy and actually abandoning the equilibrium to which it was initialized. Hence, one could speak of an 'inverted fluctuation theorem' that is satisfied here.

In the following we want to investigate how it is possible for this self-organizing system to produce negative entropy. We hypothesize that the negative entropy production is based on

(a) no stopping,  $\langle (t_1 - t_0)\Omega \rangle \approx 0.06$ ,  $n \approx 8.6 \times 10^6$

(b) stopping,  $\langle (t_1 - t_0)\Omega \rangle \approx -3.09$ ,  $n \approx 4.1 \times 10^5$

Figure 6: Distributions of the entropy production for an early time interval during the transient ( $t_0 = 15$ ,  $t_1 = 20$ ,  $T = 909.1$ ) classified according to whether a stopping agent was observed during the measurement.

fluctuations and the stopping behavior of the agents, hence, a process of frozen accidents. Note that such a mechanism is similar to the famous thought experiment 'Maxwell's Demon' (Maxwell, 1871). Furthermore, an implementation of Maxwell's Demon was reported (Bannerman et al., 2009) that is used as a cooling technique (cf. our metaphor of a heat pump in the introduction). Here we have rather a 'distributed demon' embodied by many autonomous agents that control themselves (Adami (1998) applies a similar argument to evolution). BEECLUST does not sort particles or agents as Maxwell's Demon but aggregate them (i.e., we generate uneven density distributions).

We measure the entropy production within a limited time interval  $[t_0 = 15, t_1 = 20]$  in the early transient. In addition, we classify for each measurement whether at least one agent changed its state from moving to stopped (starting agents do not occur that early in the simulation). The entropy production distribution for these two classes are shown in Fig. 6. For the measurements without a stopping agent the averaged change in the density modulation is about 0 ( $\langle (t_1 - t_0)\Omega \rangle \approx 0.06$ ). In contrast, for those measurements with stopping agents the averaged change of density modulation is negative ( $\langle (t_1 - t_0)\Omega \rangle \approx -3.09$ ) indicating frozen accidents. For much later time intervals no difference between measurements with stopped and without a stopping agents are found. The negative value of  $\langle (t_1 - t_0)\Omega \rangle$  demands for clarification because in the limit  $t \rightarrow \infty$  the average density modulation is positive.

Figure 8: Evolution of the agent density modulation over time, black line shows ensemble average, gray lines show samples, insert shows details of the ensemble average within the first 250 time steps.

The explanation is a special feature of the BEECLUST-controlled swarm in this scenario which consists of three phases (see Fig. 7). In the short period before the first cluster forms, the average entropy production is  $\Omega = 0$  indicating that the original fluctuation theorem holds for this phase. The first cluster usually does not form close to the global optima but relatively close to the middle of the arena, see Fig. 7(a). In this area the agent density modulation (eq. 7) contributes negatively. In a second phase the average density modulation is negative ( $\Omega < 0$ ) because the density close to the middle of the arena increases further, see Fig. 7(b). This is also indicated by the evolution of the agent density modulation over time as shown in Fig. 8. Initially it stays close to 0 and only later it clearly takes a positive sign. The insert shows details of the first 250 time steps and indicates negative slope for the time interval  $[15, 20]$  (i.e., second phase) of Fig. 6. Only later the clusters ‘move’ towards the ends of the arena probably due to wall effects, see Fig. 7(c) and consequently the average density modulation is positive ( $\Omega > 0$ ).

### Discussion

Note again that  $\rho(k, t) = 0$  corresponds to maximum entropy. Therefore, any  $\rho(k, t) \neq 0$  in Fig. 8 indicates negative entropy production. We conclude that the negative entropy production of this system is initiated by entropy fluctuations which are normally distributed and are negative/positive with about the same probability respectively according to the original fluctuation theorem and as seen in Fig. 6(a). Some of these ‘negative entropy production’-events are locally observable by the agents themselves because there are three agent-to-agent encounters with mutual perception. This local perception of the global measure of entropy is leveraged by stopping all three agents and stores the local entropy fluctuation. Cascades of such stopping behaviors generate a positive feedback (self-amplification of fluctuations as in Rayleigh-Bénard convection). In the end,

Figure 9: Sample run of a simple model based on summations of  $N = 25$  random processes initialized to  $X_i(0) = 0$  and based on normally distributed random variables ( $\mu = 0$ ,  $\sigma^2 = 1$ ).

a system dynamics is generated, that can be described by an inverted fluctuation theorem, which dictates an exponentially increasing probability of low entropy states. Hence, this emergent self-organizing swarm does indeed rely on frozen accidents. Note that the overall system still produces positive entropy (e.g., due to accelerations of the agents) while the agent-position-based entropy is only reduced in the self-organizing sub-system.

The effectiveness of the frozen-accidents concept can easily be made clear by a simple model. We represent the entropy contribution of each agent  $i$  by a random process  $X_i(t)$ . The total entropy is just the sum  $\sum_{i=0}^N X_i(t)$  over all agents  $N$ . The restriction of all random processes to the interval  $[-5, 5]$  is essential and we define  $X_i(t) = 5$ ,  $\forall t > t_0$  with  $t_0$  is the first time agent  $i$  achieved  $X_i(t_0) = 5$ . That is, once a random process reaches  $X_i(t_0) = 5$  (a local property) it stays there forever—a frozen accident. As a consequence the number of active random processes  $N_a$  will decrease monotonically. A sample run of this simple model for  $N = 25$  based on Gaussian distributed  $X_i$  and initialization  $X_i(0) = 0$  is shown in Fig. 9. The bias in the otherwise random trajectory is noticeable. Note that the summation of Gaussian distributed random variables  $\sum_N X_i$  with each having a variance of  $\sigma_i^2$  results in a random variable that is also Gaussian distributed with a variance of  $\sigma^2 = \sum_N \sigma_i^2$ . With decreasing number of active processes  $N_a$  more and more variances vanish ( $\sigma_i^2 = 0$ ). Hence, also the variance of the sum will decrease which is the macroscopic effect of the frozen accidents and ensures that states of low entropy are much more likely to be maintained.

The results shown in Figs. 4, 5, and 6(b) indicate that this emergent self-organized system obeys an inversion of the fluctuation theorem which could be stated as

$$\lim_{t \rightarrow \infty} \frac{1}{t} \ln \frac{P[\bar{\Sigma}_t = -A]}{P[\bar{\Sigma}_t = A]} = A, \quad (11)$$

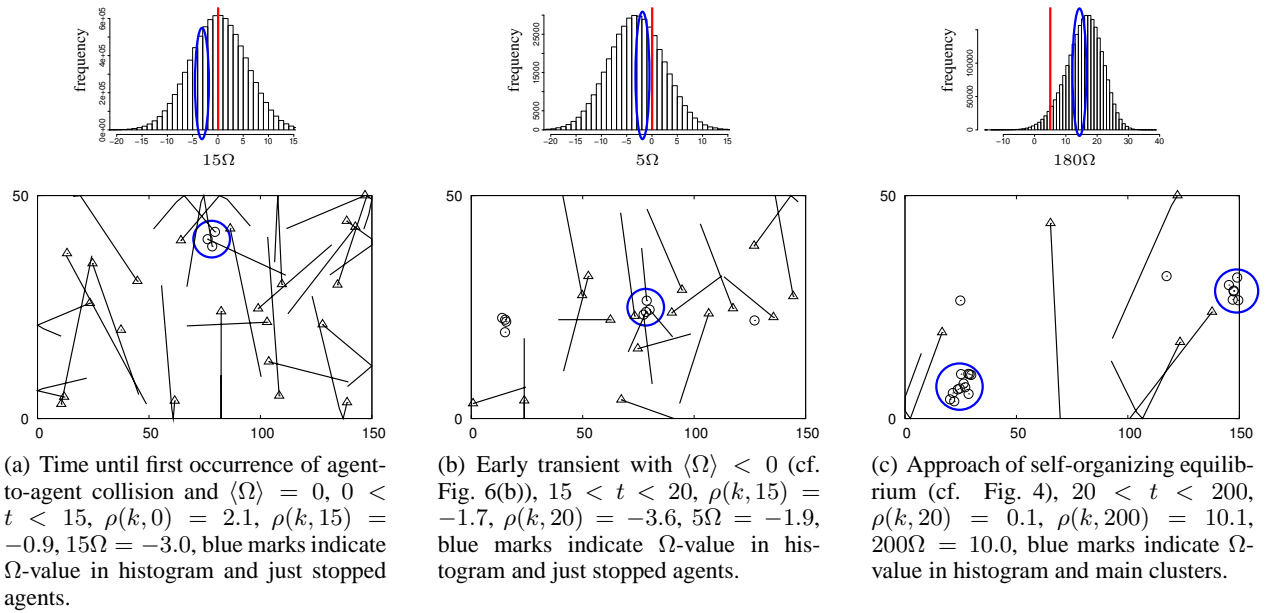

Figure 7: The three phases observed in the investigated scenario each with a representative entropy production histogram and a plot of the arena showing moving (triangles) and stopped agents (circles) with a line indicating their most recent trajectory (histograms are meant to be qualitative).

following eq. 3. We get an immediate interpretation of this self-organizing system by inverting the interpretation of the fluctuation theorem. A self-organizing system that is started with high entropy will produce negative entropy with an exponentially increasing probability over time. As a consequence there is a ‘self-organization equilibrium’ of lower entropy to which the system will converge. As a second consequence the self-organizing entropy-reduction behavior is a transient phenomenon, cf. (Prigogine, 1997, p. 62).

## Conclusion

In this paper, we have analyzed an emergent self-organizing multi-agent (or swarm) system controlled by the BEECLUST algorithm with methods based on and suggested by the fluctuation theorem. The results provide empirical evidence for the existence of an inverted fluctuation theorem that applies for such dissipative self-organizing systems. In addition, this work suggests the rich and thought-provoking metaphor of considering emergent swarm systems as implementations of a ‘distributed Maxwell’s demon’ because random events are leveraged by autonomous decisions of embodied agents based on locally measured samples of a global entropy change. A theory based on an inverted fluctuation theorem could prepare a wide basis for the analysis of self-organizing systems. We claim these methods have a potential for general applicability. For example, in flocking dissipation occurs due to rotational accelerations and averaging of directions (loss of information). Potential generalization is also indicated by preliminary results in

other scenarios which will be reported in future work.

Specific exemplary benefits of such a theory could be the definition of preconditions for self-organization, for example, concerning the cognitive abilities of the agents. Statistical properties of fluctuations describe the time-scales on which negative entropy production can be observed. The agents need to perceive local samples of this global property of negative entropy production and need to react within these time-scales. Hence, conditions for controller sampling rates could be derived. The agents need appropriate sensors that allow local measurements of entropy with an accuracy that is sufficiently higher than the rate at which events of negative entropy production occur. Thus, conditions for successfully generating positive feedbacks could be derived.

Especially the origin of BEECLUST confirms the possibility of applying the proposed methods to natural systems such as clustering behaviors in young honey bees (Szopek et al., 2008) or other social insects, as well as flocks, herds, and shoals. Hence, the same methods could be used for artificial and natural systems which could, in turn, enrich primarily biological studies.

This work proved again that thermodynamics offers many fully developed methods which can often be applied even unmodified to problems of emergent behavior (cf. Hamann et al. (2011a)). Pursuing this research track might be a promising way of achieving general insights to still rather fuzzy concepts such as emergence or self-organization.

Finally, it is clear that the reported approach is truly interdisciplinary in combining methods and problems from physics,

biology, and computer science. It is obvious that, at least in the field of artificial life, any future research success has to be founded on a collection of several scientific fields. In our future work, we hope to continue this approach by generalizing the concept of an inverted fluctuation theorem for emergent self-organizing multi-agent systems.

## Abstract

A system of interacting elements can be represented by a directed network so that elements are nodes and interaction between two elements is an arc. Conventionally, each node is just a point, each arc represents some kind of interaction between two nodes and nothing more after the system is mapped to a directed network. However, in many real systems, each element has its own intra-node process and interaction between two elements can be seen as an interface between two intra-node processes. We can formalize this idea “objects as processes, interactions as interfaces” within the framework of category theory. We show that a new notion of connectedness called *lateral connectedness* emerges as a canonical structure obtained from the idea. Lateral connectedness is not defined on the set of nodes of a directed network, but on the set of arcs. By its definition, it may be associated with functional commonality between arcs emerging from shared input or output. As a first application, we examine significance of lateral connectedness in the neuronal network of the nematode *Caenorhabditis elegans* by comparing the partition of the set of arcs induced by the connectedness and the partitions based on neuron functions. Lateral connectedness can capture a part of functional segregation of the neuronal network above a certain interaction strength level.

## Introduction

Science of complex networks is one promising approach to understand the intrinsic organization of living systems (Alon, 2006; Junker and Schreiber, 2008; Sporns, 2011). Many characteristics such as degree distributions, average path length, clustering coefficients, centralities, assortativity coefficient, network motifs have been introduced in order to reveal functionality of biological, social, technological systems from network topology (Boccaletti et al., 2006; Newman et al., 2006; Newman, 2010). These characteristics are based on the idea which I would like to call the *real view* on networks: each node is just a point and edges or arcs between nodes indicate the existence of some kind of interaction between nodes if a system is represented as a network. However, in many real systems, it is the case that some kind of process is running within an object represented by a node. For example, in neuronal networks, nodes are neurons that have information processing ability.

In gene regulation networks, nodes are genes, but we should include proteins coded by those genes into nodes if we consider regulation relationships as arcs. Thus, we can think that complicated chemical processes to synthesize proteins occur within each node in a gene regulation network. We can interpret other biological networks including ecological networks, metabolic networks in the same way. If we consider objects as processes, then interactions between objects can be seen as interfaces between processes. I would like to call this view “objects as processes, interactions as interfaces” on networks the *dual view* in contrast to the ordinary real view mentioned above.

In this paper, we examine what is involved in having internal processes on nodes in general for complex networks. Usually, processes occurring on nodes are described as particular dynamics. Then, an appropriate statistical ensemble of dynamics is studied in order to conclude something in general (e.g. random Boolean networks by (Kauffman, 1969)). Instead of statistical generality, we here appeal to category theoretical universality to study the problem.

We note that there is an inverse dual view, namely, “processes as objects”. This idea appears in the formulation of Metabolism-Repair System by R. Rosen (Rosen, 1958). Recently, the idea was used as the line graph transformation in the community detection problem in complex networks (Ahn et al., 2010; Evans and Lambiotte, 2009). The two ideas “objects as processes” and “processes as objects” have a certain dual relationship called category theoretical adjunction (MacLane, 1998) if they are formalized within the framework of category theory (Haruna and Gunji, 2007; Pultr, 1979).

There are many ways (indeed, uncountably many ways) to consider objects as processes. However, we can show that there exists a canonical way (in a precise mathematical sense stated in Section 3) among all the ways to see objects as processes within the framework of category theory (Haruna, 2011b). The canonical way to see objects as processes gives rise to an equivalence relation on the set of arcs of each directed network. This equivalence relation can be interpreted as defining a new notion of connectedness called *lateral con-*

Figure 1: The idea “objects as processes, interactions as interfaces”.

*nectedness*. An intuitive explanation of derivation of lateral connectedness without category theory is the main aim of the former half of this paper. In the latter half, we analyze the neuronal network of the nematode *Caenorhabditis elegans* based on lateral connectedness as a first application to real world networks.

This paper is organized as follows. In section 2, we describe a mathematical formulation of the dual view on directed networks. In section 3, we introduce lateral connectedness for directed networks as a naturally emerging structure from the dual view. In section 4, we apply lateral connectedness to the neuronal network of *C. elegans* and discuss its functional significance. In section 5, we give conclusions and outlooks.

## Objects as Processes, Interactions as Interfaces

In this paper, we only consider directed networks. Some early attempts related to the content of this section are found in Haruna and Gunji (2007); Haruna (2008a,b, 2011a).

In the dual view introduced in Section 1, each node is interpreted as a process and each arc is seen as an interface between two processes. This idea can be formalized as network transformations as follows.

As a motivating example, let us interpret each node as an arc (together with its source and target nodes) representing a process running in the node and each arc as a node connecting two arcs representing processes running in the original two nodes (Fig. 1). Of course, each node can be replaced by a much more complicated network representing a process running within the node. The connection between the two complicated networks can also be arbitrary. We call a network (that can be arbitrary complicated) representing a process running within a node together with information

Figure 2: Three examples of the calculation of the network transformation  $L$ .

how its two copies form an interface corresponding to an arc a *model of directed network type*. In general, models of directed network type need not consist of directed networks (Haruna, 2011b), however, in the following discussion, we restrict ourselves on models consisting of directed networks for simplicity.

Fig. 2 illustrates how the above motivating model of directed network type gives rise to a network transformation  $L$ . In Fig. 2 (a), the two nodes  $x$  and  $y$  are converted to two arcs  $x$  and  $y$  by  $L$ . The target of  $x$  and the source of  $y$  are glued by the arc  $f$  in the original network. In Fig. 2 (b), there are three copies of arcs  $x$ ,  $y$  and  $z$  after the transformation  $L$  corresponding to the three nodes  $x$ ,  $y$  and  $z$  in the original network. Their sources and targets are glued according to the arcs  $f$  and  $g$  in the original network. The similar copy and glue rule works for the example in Fig. 2 (c).

Formally, the network transformation  $L$  can be defined as follows. Let  $G = (A, O, \partial_0, \partial_1)$  be a directed network, where  $A$  is a set of arcs,  $O$  is a set of nodes and  $\partial_0$  and  $\partial_1$  are maps from the set  $A$  to the set  $O$  that send each arc to its source node and target node, respectively. The directed network  $L(G)$  obtained by the application of  $L$  to  $G$  is a quartet  $L(G) = (O, O \times \{0, 1\} / \sim, \partial'_0, \partial'_1)$ , where the set of arcs of  $L(G)$  is identical to the set of nodes  $O$  of  $G$ , the set of nodes of  $L(G)$  is a quotient set  $O \times \{0, 1\} / \sim$  and

Figure 3: The map  $\varphi_G$  materialize the idea “interaction as interface”.

$\sim$  is an equivalence relation on the set  $O \times \{0, 1\}$  generated by the relation defined by  $(x, 1) \sim (y, 0)$  if and only if there exists an arc  $f$  from  $x$  to  $y$  in  $G$ . The symbol 1 indicates the “source part” of the node  $x$  and the symbol 0 indicates the “target part” of the node  $y$ . The source and target maps  $\partial'_0, \partial'_1$  are defined naturally.

In general, for any model of directed network type, the induced network transformation can be described by a similar copy and glue rule, no matter how complicated it is. For a category theoretical formulation, see (Haruna, 2011a).

### A New Notion of Connectedness

By the network transformation  $L$  introduced in Section 2, each node in a directed network  $G$  is sent to an arc in  $L(G)$ . On the other hand, we can think that each arc  $f$  in a directed network  $G = (A, O, \partial_0, \partial_1)$  is mapped to a node in  $L(G)$  between two arcs in  $L(G)$  corresponding to the source and the target nodes of  $f$ , namely,  $\partial_0 f$  and  $\partial_1 f$  (Fig. 3). We denote this map by  $\varphi_G : A \rightarrow O \times \{0, 1\} / \sim$ . For each arc  $f \in A$ ,  $\varphi_G(f)$  is the target of  $\partial_0 f$  (or the source of  $\partial_1 f$ ) in  $L(G)$ . Hence, we have  $\varphi_G(f) = [(\partial_0 f, 1)] = [(\partial_1 f, 0)]$ , where  $[(x, i)]$  is an equivalence class containing  $(x, i) \in O \times \{0, 1\}$ .

A natural question about the nature of the map  $\varphi_G$  is “When does  $\varphi_G(f) = \varphi_G(g)$  hold for arcs  $f, g \in A$ ?” The answer is straightforward and the necessary and sufficient condition for the equality  $\varphi_G(f) = \varphi_G(g)$  is that there exists a zigzag sequence of arcs between  $f$  and  $g$  as indicated in Fig. 4. We say that two arcs  $f$  and  $g$  are *laterally connected* if  $\varphi_G(f) = \varphi_G(g)$  holds.

For any model of directed network type, a similar map on the set of arcs of a given directed network can be defined. Such a map induces an equivalence relation on the set of arcs by identifying two arcs if they are sent to the same element in the codomain of the map. Let us denote the equivalence relation induced by the map  $\varphi_G$  above by  $R_{LC}$ . Then,  $R_{LC}$  is canonical in the following sense. *For any directed network  $G = (A, O, \partial_0, \partial_1)$ ,  $R_{LC}$  is the smallest equivalence relation on the set of arcs  $A$  among those induced by all models of directed network type.* In other words, the partition of the set of arcs induced by lateral connectedness is the finest one among those induced by the idea “objects as processes, interactions as interfaces”. We call each equiva-

Figure 4: Two arcs  $f$  and  $g$  are laterally connected if there is a zigzag sequence of arcs between them. There are four cases depending on the situations at the both ends.

lence class *laterally connected component*. This statement can be proved within the framework of category theory in more general form (Haruna, 2011b).

In summary, we obtain the notion of lateral connectedness as a canonically emerging structure of directed networks from the idea “objects as processes, interactions as interfaces”.

By its definition, lateral connectedness may be relevant with functional commonality between arcs emerging from shared input or output. This is in contrast to the notion of strong connectedness. Here we say that two arcs are strongly connected if one arc can be reached from the other by a directed path and vice versa. Strong connectedness may be associated with functionality resulting from circulation of information or materials. Intuitively, they seem to be dual to each other. Indeed, this intuition can be enhanced by the following category theoretical point of view.

Lateral connectedness derives from the network transformation  $L$  which is based on the idea “objects as processes, interactions as interfaces”. On the other hand, strong connectedness can be obtained from the line graph transformation  $R$  which is based on the idea “processes as objects”. Given a directed network  $G = (A, O, \partial_0, \partial_1)$ , its line graph is a directed network  $R(G) = (S, A, \partial'_0, \partial'_1)$ , where  $S = \{(f, g) \in A \times A \mid \partial_1 f = \partial_0 g\}$ ,  $\partial'_0(f, g) = f$  and  $\partial'_1(f, g) = g$  for any  $(f, g) \in S$ . As noted in Section 1, the two transformations  $L$  and  $R$  satisfy a certain category theoretical duality called adjunction (Haruna and Gunji, 2007;

Figure 5: The wiring diagram of the neuronal network of *C. elegans* based on the database (Oshio et al., 2003) (<http://ims.dse.ibaraki.ac.jp/ccep/>) depicted by Graphviz (<http://www.graphviz.org/>). (a) Arcs are colored based on pairs of functions of their source and target neurons. (b) Correspondence between colors and pairs of functions of neurons.

Pultr, 1979). By definition,  $S$  is the set of arcs of the directed network  $R(G)$ , but it can be seen as a binary relation on the set  $A$ . Mathematically, the notion of strong connectedness defined above is an equivalence relation  $SC$  on the set  $A$  of arcs of  $G$ . On the other hand, we have an equality

$$SC = \overline{S} \cap \overline{S^{-1}}, \quad (1)$$

where  $S^{-1}$  is the inverse of the binary relation  $S$  and  $\overline{T}$  for a binary relation  $T$  on  $A$  is its reflexive and transitive closure. In this sense, strong connectedness is generated by the line graph transformation  $R$  which is category theoretical dual to  $L$ .

One might think that the duality between lateral connectedness and strong connectedness in the above sense is a mathematical expression for Lorente de Nó's two principles of plurality and reciprocity (Lorente de Nó, 1938).

## Analysis of a Neuronal Network

In this section, we discuss significance of lateral connectedness in the neuronal network of *C. elegans* as a first application of it. We compare the partitions of the set of arcs based on functions of neurons with the partition induced by lateral connectedness to examine functional significance of lateral connectedness. We make use of two similarity measures described in the next subsection for the comparison.

### Network Data

We make use of the database constructed by Oshio et al. (2003) (<http://ims.dse.ibaraki.ac.jp/ccep/>) whose original reference is White et al. (1986). We remove nodes and connections other than neurons and chemical synapses. The resulting data set contains 233 neurons among 282 neurons

in the somatic nervous system and 4170 chemical synapses. We construct a family of directed networks whose nodes are 233 neurons in the following way: First, we put an arc from one node to another node if there exists a chemical synapse from the former to the latter. Second, since there is multiple chemical synapses from one neuron to another neuron in general, we specify a weight for each arc by the number of chemical synapses from the source to the target of the arc. Finally, we introduce thresholds for the weight values and consider the network topology consisting of arcs whose weights are greater or equal to a given threshold.

Each neuron has one of three functional types: sensory, inter and motor. We consider three partitions of the set of arcs based on the functions of neurons. The first one is called *ST-partition* which considers types of the two neurons at both ends of each arc. Thus, there are nine clusters for the ST-partition. In the wiring diagram shown in Fig. 5 (a) where threshold is 1, each arc is colored based on the ST-partition. The correspondence between colors and the ST-partition clusters is indicated in Fig. 5 (b). The second one is called the *S-partition* which considers type of the source neuron of each arc. The third one is called the *T-partition* which considers type of the target neuron of each arc. The number of clusters in the S-partition or T-partition is three.

The equivalence relation  $R_{LC}$  induced by lateral connectedness also gives rise to a partition of the set of arcs. We call this partition the *LC-partition*. In the following discussion, we measure similarity between the LC-partition and the above three functional partitions.

### Similarity Measures

We make use of two similarity measures to quantify similarity between two partitions on a set. The first one is called the

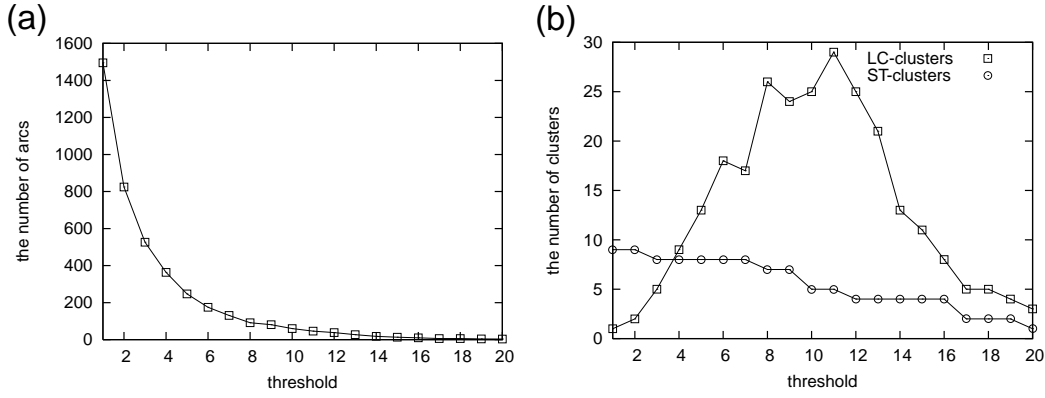

Figure 6: (a) The number of arcs as a function of threshold. (b) The number of clusters in the LC-partition and in the ST-partition as a function of threshold.

*Adjusted Rand Index (ARI)* (Hubert and Arabie, 1985). The second one is called the *Adjusted normalized Mutual Information (AMI)* (Vinh et al., 2009). To explain the idea of the ARI, we first review the definition of the *Rand Index (RI)* (Rand, 1971).

Let  $X$  be a set consisting of  $N$  points. Let  $\mathbf{U} = \{U_1, U_2, \dots, U_l\}$  and  $\mathbf{V} = \{V_1, V_2, \dots, V_m\}$  be two partitions of  $X$ , namely, they are families of subsets of  $X$  satisfying  $U_i \cap U_{i'} = V_j \cap V_{j'} = \emptyset$  for  $i \neq i', j \neq j'$  and  $\cup_{i=1}^l U_i = \cup_{j=1}^m V_j = X$ . Let us put  $n_{ij} := |U_i \cap V_j|$ ,  $a_i := |U_i|$  and  $b_j := |V_j|$  for  $i = 1, 2, \dots, l$  and  $j = 1, 2, \dots, m$ , where  $|Y|$  for a set  $Y$  denotes its cardinality. Then, we have  $a_i = \sum_{j=1}^m n_{ij}$  and  $b_j = \sum_{i=1}^l n_{ij}$  for  $i = 1, 2, \dots, l$  and  $j = 1, 2, \dots, m$ . A  $l \times m$  matrix  $C := (n_{ij})$  is called the *contingency matrix*, which encodes information how two partitions  $\mathbf{U}$  and  $\mathbf{V}$  overlap. We can calculate both the ARI and the AMI by using elements of the contingency matrix  $C$ .

The Rand Index (RI) between partitions  $\mathbf{U}$  and  $\mathbf{V}$  is defined by counting the number of pairs of elements of  $X$  on which two partitions agree or disagree:

$$RI(\mathbf{U}, \mathbf{V}) = \frac{N_{00} + N_{11}}{N_{00} + N_{01} + N_{10} + N_{11}}, \quad (2)$$

where  $N_{00}$  is the number of pairs that are in the same cluster in both  $\mathbf{U}$  and  $\mathbf{V}$ ,  $N_{01}$  is the number of pairs that are in the same cluster in  $\mathbf{U}$  but in different clusters in  $\mathbf{V}$ ,  $N_{10}$  is the number of pairs that are in different clusters in  $\mathbf{U}$  but in the same cluster in  $\mathbf{V}$  and  $N_{11}$  is the number of pairs that are in different clusters in both  $\mathbf{U}$  and  $\mathbf{V}$ . After a few algebras, one can see that  $N_{01}$  and  $N_{10}$  are given by

$$N_{01} = \sum_{j=1}^m \binom{b_j}{2} - \sum_{i=1}^l \sum_{j=1}^m \binom{n_{ij}}{2}, \quad (3)$$

$$N_{10} = \sum_{i=1}^l \binom{a_i}{2} - \sum_{i=1}^l \sum_{j=1}^m \binom{n_{ij}}{2}. \quad (4)$$

Since we have  $N_{00} + N_{01} + N_{10} + N_{11} = \binom{N}{2}$ , we obtain the following explicit formula for the RI:

$$RI(\mathbf{U}, \mathbf{V}) = \frac{\binom{N}{2} - \left\{ \sum_i \binom{a_i}{2} + \sum_j \binom{b_j}{2} \right\} + 2 \sum_{i,j} \binom{n_{ij}}{2}}{\binom{N}{2}}. \quad (5)$$

The RI takes its maximum value 1 when two partitions are identical. The minimum value 0 is taken if and only if one partition consists of a single cluster and the other consists of only clusters with a single point, which is hard to satisfy by random partitions. Indeed, the RI takes relatively high values for two random partitions. However, it is plausible for a similarity measure to take values close to zero for random partitions. To improve this disadvantage of the RI, Hubert and Arabie (1985) introduced the Adjusted Rand Index (ARI) which takes over a correction for chance:

$$ARI(\mathbf{U}, \mathbf{V}) = \frac{RI(\mathbf{U}, \mathbf{V}) - E(RI|\mathbf{a}, \mathbf{b})}{1 - E(RI|\mathbf{a}, \mathbf{b})}, \quad (6)$$

where 1 in the denominator is the maximum value of the RI and  $E(RI|\mathbf{a}, \mathbf{b})$  is the expected value of the RI between two randomly chosen partitions of the set  $X$  subject to the condition that two vectors  $\mathbf{a} = (a_1, a_2, \dots, a_l)$  and  $\mathbf{b} = (b_1, b_2, \dots, b_m)$  are fixed. Since we have  $E\left(\binom{n_{ij}}{2} | \mathbf{a}, \mathbf{b}\right) = \binom{a_i}{2} \binom{b_j}{2} / \binom{N}{2}$  (Hubert and Arabie, 1985), an explicit formula for the ARI is given by

$$ARI(\mathbf{U}, \mathbf{V}) = \frac{\sum_{i,j} \binom{n_{ij}}{2} - \left\{ \sum_i \binom{a_i}{2} \sum_j \binom{b_j}{2} \right\} / \binom{N}{2}}{\frac{1}{2} \left\{ \sum_i \binom{a_i}{2} + \sum_j \binom{b_j}{2} \right\} - \left\{ \sum_i \binom{a_i}{2} \sum_j \binom{b_j}{2} \right\} / \binom{N}{2}}. \quad (7)$$

Our second measure of similarity, the AMI is defined based on the mutual information between two partitions (Vinh et al., 2009). Let us introduce the probability that an element of  $X$  is contained in a cluster  $U_i$  by  $P(i) = a_i/N$ .

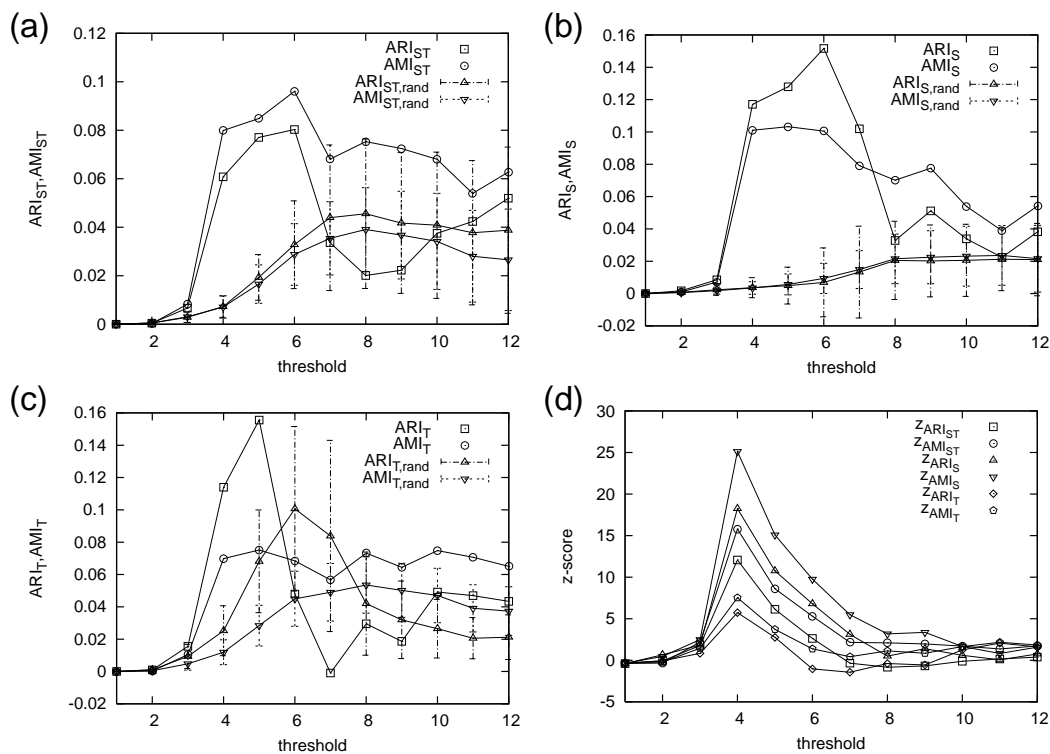

Figure 7: Comparisons between the LC-partition and partitions based on neuron functions. Two similarity measures, one is pair-counting based (the ARI) and the other is information-theoretic (the AMI), are used. (a) The LC-partition vs the ST-partition. (b) The LC-partition vs the S-partition. (c) The LC-partition vs the T-partition. (d) Z-scores for the values of two similarity measures as functions of threshold.

The Shannon entropy with respect to the partition  $\mathbf{U}$  is defined by  $H(\mathbf{U}) = -\sum_{i=1}^l P(i) \log_2 P(i)$ . Similarly, the Shannon entropy with respect to the partition  $\mathbf{V}$  is given by  $H(\mathbf{V}) = -\sum_{j=1}^m P'(j) \log_2 P'(j)$ , where  $P'(j) = b_j/N$ . Then, the mutual information between two partitions  $\mathbf{U}$  and  $\mathbf{V}$  is defined by  $I(\mathbf{U}, \mathbf{V}) = \sum_{i=1}^l \sum_{j=1}^m P(i, j) \log_2 \frac{P(i, j)}{P(i)P'(j)}$ , where  $P(i, j) = n_{ij}/N$  which is the joint probability that an element of  $X$  falls into both  $U_i$  and  $V_j$ .

Strehl and Ghosh (2002) proposed the normalized mutual information (NMI) as follows:

$$NMI(\mathbf{U}, \mathbf{V}) = \frac{I(\mathbf{U}, \mathbf{V})}{\sqrt{H(\mathbf{U})H(\mathbf{V})}}, \quad (8)$$

which takes its values in the unit interval  $[0, 1]$ . The NMI takes its maximum value 1 when two partitions are identical. The minimum value 0 is realized when two partitions are independent, namely,  $n_{ij} = a_i b_j$  holds for all  $1 \leq i \leq l$  and  $1 \leq j \leq m$ . Hence, the NMI for random partitions takes its values close to 0. However, its adjusted version is more preferable. The adjusted normalized mutual information (AMI) is defined in the similar spirit as in the ARI (Vinh

et al., 2009) :

$$AMI(\mathbf{U}, \mathbf{V}) = \frac{I(\mathbf{U}, \mathbf{V}) - E(I|\mathbf{a}, \mathbf{b})}{\sqrt{H(\mathbf{U})H(\mathbf{V}) - E(I|\mathbf{a}, \mathbf{b})}}, \quad (9)$$

where  $E(I|\mathbf{a}, \mathbf{b})$  is the expected value of the mutual information  $I$  between two randomly chosen partitions of the set  $X$  subject to the condition that two vectors  $\mathbf{a} = (a_1, a_2, \dots, a_l)$  and  $\mathbf{b} = (b_1, b_2, \dots, b_m)$  are fixed.

In the next subsection, we apply these two adjusted similarity measures, the ARI and the AMI, to the partitions of the set of arcs in the neuronal network of *C. elegans* by neuron functions and the partition based on lateral connectedness for each threshold.

## Results

Fig. 6 (a) shows the number of arcs as a function of threshold. Fig. 6 (b) indicates the number of clusters in the LC-partition and in the ST-partition. The former tends to increase for thresholds within the range from 1 to 10 because decrease in the number of arcs can lead to division of one cluster into two or more clusters. It decreases for thresholds larger than 12 simply because the number of arcs is too small

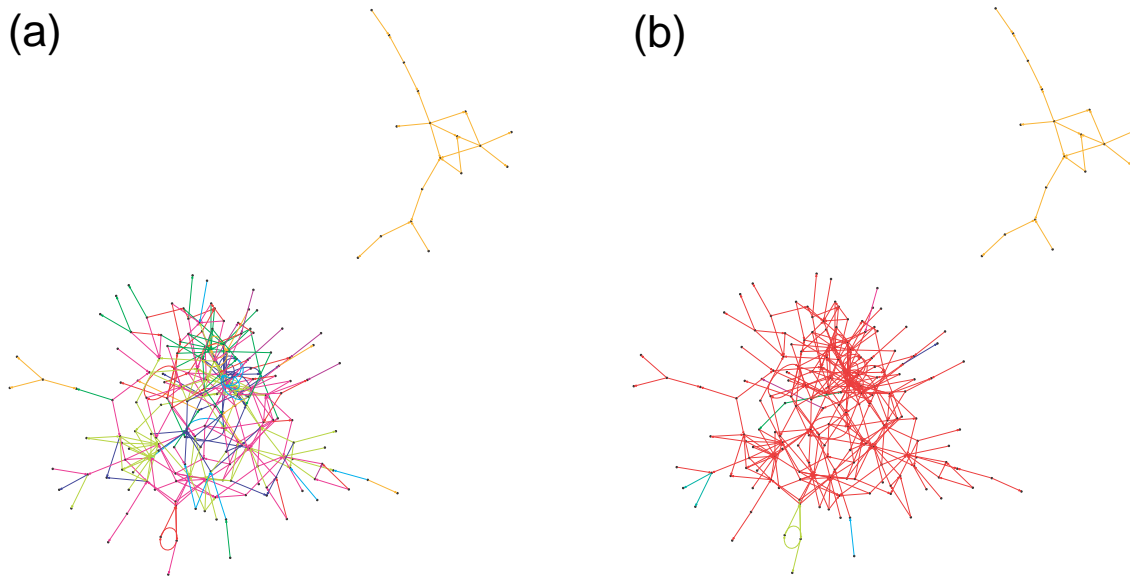

Figure 8: The wiring diagram of the neuronal network of *C. elegans* at threshold 4 depicted by Graphviz (<http://www.graphviz.org/>). (a) Arcs are colored by the ST-partition. Color assignment is the same for Fig. 5. (b) Arcs are colored by the LC-partition. Colors of different clusters are specified arbitrarily.

for the number of the LC-clusters to grow by divisions for those relatively large thresholds.

In Fig. 7 (a), we plot the ARI and the AMI between the LC-partition and the ST-partition as a function of threshold. It takes its maximum value when threshold is equal to 6. As a control experiment, we calculate averages and standard deviations of the ARI and the AMI between the LC-partition and the ST-partition on 1000 randomized networks by re-wiring arcs randomly, which are also shown in Fig. 7 (a). Note that degree distributions are invariant under the re-wiring process. We can see a large deviation from the control around the maximum point. We have similar results for the S-partition and the T-partition (Fig. 7 (b),(c)).

To quantify deviation from the control experiment, we calculate the Z-score for each comparison. The Z-score of a quantity  $Q$  is defined by

$$z_Q = \frac{Q_{orig} - \langle Q_{rand} \rangle}{\sigma}, \quad (10)$$

where  $Q_{orig}$  is the value of  $Q$  in the original network,  $\langle Q_{rand} \rangle$  is the average of  $Q$  calculated from an ensemble of randomized networks and  $\sigma$  is its standard deviation. The Z-scores of both the ARI and the AMI take their maximum value when threshold is equal to 4 for all comparisons (Fig. 7 (d)). All of the maximum values of the Z-scores are more than 5, which indicates significant deviation from the control in all comparisons. However, we should note that the absolute values of the two similarity measures are not so high, at most 0.152.

In Fig. 8, we plot the wiring diagram where we set thresh-

old 4. Arcs are colored based on the ST-partition (Fig. 8 (a)) and the LC-partition (Fig. 8 (b)). There are two weakly connected components, one is large and the other is small. Here, we define a weakly connected component of a directed network as a maximal set of arcs in which every pair of arcs are connected by a sequence of arcs ignoring the direction. Almost all the motor-motor connections are included in the smaller weakly connected component on one hand, they also form a single laterally connected component in the LC-partition. However, the LC-partition fails to capture more detailed functional partition within the larger weakly connected component possibly due to many recurrent connections between the sensor, inter and motor region of the neuronal network of *C. elegans* (Varshney et al., 2011). This is one reason that we have relatively low absolute values for the two similarity measures.

## Conclusions and Outlooks

In this paper, we intuitively explained that how the idea “objects as processes, interactions as interfaces” can be formalized within the framework of category theory. We derived the notion of lateral connectedness as a canonical structure obtained from the idea. By its definition, lateral connectedness has possibility to be associated with functional commonality between arcs arising from shared input or output. As a first application of lateral connectedness, we examined functional significance of lateral connectedness in the neuronal network of *C. elegans* by the method of clustering comparison. For the analysis, we made use of two similarity measures to quantify similarity between two partitions

on the same set, one is pair-counting based measure and the other is information-theoretic measure.

We showed that the partition of the set of arcs based on lateral connectedness is not inconsistent with the functional partition of the set of arcs. However, even if we set threshold at the point where the largest deviation from an ensemble of randomized networks is observed, it can only capture a part of the partitions based on neuron functions. One problem of the analysis performed in this paper may be that the direct comparison to functional partitions is too strict to recognize significance of lateral connectedness. Another problem is that the data used is incomplete. Analysis with more complete data (Varshney et al., 2011) will be necessary.

Introduction of lateral connectedness has several implications. First, we can analytically solve percolation problems with respect to lateral connectedness on configuration model (networks chosen uniformly at random from the set of all possible networks with a specified degree distribution) of directed networks (Haruna, 2011b). Applications of the analytical result on configuration model to biological networks are now ongoing. Second, we can define alternatives for some notions used in conventional complex network studies. For example, the notion of path length can be defined based on lateral connectedness. Since metrics such as closeness and betweenness centralities are functions of path lengths, they are also the targets of alternative definitions. Finally, theoretical development and empirical applications of the duality between lateral connectedness and strong connectedness are also intriguing issues.

# Opening Stable Doors: Complexity and Stability in Nonlinear Systems

Inman Harvey<sup>1</sup>

<sup>1</sup>Evolutionary and Adaptive Systems Group, University of Sussex  
inmanh@gmail.com

## Abstract

Generic complex systems of many interacting parts can model both natural and artificial systems, and the conditions for their stability are of interest. Two influential papers (Gardner and Ashby, 1970; May, 1972) laid down a mathematical framework suggesting that, without some specific constraints on the interactions, such systems are very likely to be unstable as they increase in size and connectance. We draw attention to a programming error in the first paper and to flaws and omissions in reasoning in the second that discredit such conclusions when applied to nonlinear systems. With nonlinearity the connectance strength of an influence of any one variable upon any other will vary according to context, which May's analysis does not address. Further, in nonlinear systems there can be many equilibria, and global instability requires every relevant local equilibrium to be unstable; neglecting this invalidates the conclusions. We discuss the relevance of ambiguous circuits (Thomas and D'Ari, 1990) and consider simple classes of nonlinear functions that generate these, including the hat shaped viability functions that generate homeostasis in Daisyworld models. We demonstrate that the May results are unreliable even for the simplest families of nonlinear systems that model common biological, physical or artificial systems.

## Introduction

An influential early paper (Gardner and Ashby, 1970) used computer simulations to assess the probability that a large system of interacting component parts that has been assembled at random, or has grown haphazardly, will be stable or unstable. They considered systems where the interactions between parts were linear, and looked at how the expectation of stability changed as the number of variables increased. This was a theoretical study, to be motivated by its possible application to both biological and man-made systems: brains (real or artificial), planetary climate systems, social or financial systems, ecosystems. The conclusion was the suggestion that all such large (random or haphazard) complex linear dynamic systems may be expected to show the property of being stable up to some critical, fairly small, level of connections; but above that phase transition value they are overwhelmingly likely to be unstable. From this it could be deduced that if one observed large complex linear systems that were indeed stable, there must be something exceptional and non-random about the way that the parts were connected.

The influence of this work stems primarily from its extension and development by Robert May, and the subsequent proliferation of a wide body of research in this

area. He replicated a version of the results analytically rather than computationally (May, 1972), and claimed that their validity extended beyond the linear systems of Gardner and Ashby (hereafter: G&A) to systems "which in general may obey some quite nonlinear set of first-order differential equations". May's interest mainly focused on ecological systems, and a subsequent book (May, 1973) largely set the agenda for discussion of the relationship between complexity and stability in ecosystems ever since.

Before this work there was a common perception that the more diverse was the range of species in an ecosystem, the more robust and resilient to perturbations that system would be; and further, it was often assumed that this may well be due to some underlying law of large numbers that could apply very generally across all sorts of systems with many interacting components. But the work of G&A and May, apparently using very minimal mathematical assumptions, appeared to suggest that the opposite was true – at least, in the absence of further specific constraints. So subsequent argument and analysis have tended to focus on what further constraints, what limitations on the number, sign and size of interspecies interactions, might be necessary in order to make it likely that a complex ecosystem was stable. The mathematics, it has largely been assumed, is relatively simple and correct. Hence if we want to explain the existence of complex stable systems, it looks like we need to add further assumptions.

In this paper, we shall demonstrate that the reasoning within these two primary sources (Gardner and Ashby, 1970, May, 1972) is partially invalidated through omission and errors, and in particular should not be generalised in this way to nonlinear systems. Firstly, we draw attention to a programming error in the G&A paper, which has been noted previously (Solow et al., 1999). Secondly, we point out that May's attempted extension to nonlinear systems fails to specify the distribution from which the relevant connection strengths are drawn.

Thirdly, and fatally to May's reasoning, we point out a flaw where he claims to go beyond the purely linear systems of G&A towards a more general set of nonlinear systems. May considers local stability at just a single fixed point in the space of possible values for the system, a point that makes sense when considering linear systems with negative self-interactions. Unfortunately, when we move on to nonlinear systems there can be a large (and in some circumstances unlimited) number of points of potential stability to consider. Global instability would require local instability at every one of those points. Hence the probability of global stability will

be underestimated if one just considers local stability at a single fixed point, as May does.

These various criticisms are, as far as we are aware, all drawn together here for the first time. We present examples demonstrating that it is not merely exotic nonlinear functions that raise these issues. Even simple monotonic nonlinear functions such as sigmoids, or the simplest piecewise linear functions with a single change of slope, are sufficient to invalidate the reasoning. Hat shaped viability functions, as used in Daisyworld models, are discussed and it is shown how stability arises independently of the sign of the opposing effect. The ‘ambiguous circuits’ so produced are related to the multistationarity analysis of Thomas (Thomas and Kaufman, 2001a, 2001b).

These flaws in the two foundational papers by Gardner and Ashby (1970) and May (1972) suggest that a radical reappraisal is needed in the mathematical foundations of a substantial body of work that has built up over some 40 years. Rather than seeking a route to stability by adding further constraints to these abstract models, we need to open the doors to those possible locations of stability that have until now, through error or omission, been excluded. The significance goes beyond ecosystem theory to the study of all kinds of natural and artificial systems with complex nonlinear interactions, including financial systems (Haldane and May, 2011).

## Gardner and Ashby on Linear Systems

Their short paper, a Letter of less than one page in *Nature* (Gardner and Ashby, 1970), was an early example of a computer simulation, using a Monte Carlo approach. They considered a very simplified formal model of any large system of many interacting parts. This could be traffic at an airport, or the neurons in a human brain. They asked the question: supposing one did not know all the details of the interactions between component parts, but modelled these as coming from some random distribution that gave the signs and sizes of these interactions, then what was the chance that such a large system will be stable? Although in the real world most of these large systems, perhaps biological or social, will be grossly nonlinear, they explicitly restricted themselves to considering only systems with linear interactions, as a first step towards a more general treatment. They were interested only in fixed point equilibria.

The model had  $n$  component parts. The intention was to investigate how the generic properties of such systems varied as  $n$  increases. The instantaneous state of the system can be expressed by a vector  $\mathbf{x}$ , where  $x_i$  represents the current value of the  $i$ th variable. In the very general case of nonlinear systems we would have, with different nonlinear functions for each  $i$ :

$$\frac{dx_i}{dt} = \text{NonLinFn}_i(x_1, x_2, \dots, x_n)$$

However in this restricted linear case this simplifies to a weighted sum of the current values of all the variables:

$$\frac{dx_i}{dt} = \sum_j a_{ji} x_j \quad \text{Eqns 1}$$

Because this is a linear system, there is a unique equilibrium point where for all  $i$   $dx_i/dt=0$ . The issue will be: what is the

probability that this unique equilibrium is stable, given the distribution from which the weights  $a_{ji}$  in the connection matrix  $\mathbf{A}$  are drawn.  $\mathbf{A}$  is the Jacobian matrix of the first-order partial derivatives, and in this case of a linear system these terms are all scalars, of fixed size and sign; when later we move on to nonlinear systems, these terms will be variable in both size and sign.

G&A chose to make this a partially connected system, with a proportion  $C$  of the off-diagonal weights being nonzero. These nonzero weights were distributed evenly between -1.0 and +1.0. Further, they ensured that all the weights  $a_{ii}$  in the main diagonal of the connection matrix (self-connections) were negative. They distributed these evenly between -1.0 and -0.1; in May’s version that followed, May set all these to -1.0.

G&A are thus discussing a family of linear feedback systems, parameterised by these two values:  $n$ , the number of component parts, and  $C$ , the connectance or the proportion of possible interactions between parts that are non-zero. For any given values of  $n$  and  $C$ , their Monte Carlo approach involved testing many cases of such systems, with the connection weights drawn from the appropriate distributions, and finding out through computation what proportion of the systems were stable at their unique equilibrium point. For low values of the connectance, where the interactions are dominated by the stipulated negative values of self-connections, the probability of stability was close to 100% for all values of  $n$  tested. But as the connectance  $C$  increased, the probability of stability fell away. Using the limited computational facilities of their day (Gardner and Ashby, 1970), they tested examples where  $n$  equals 4, 7 or 10. Their conclusion, illustrated by a figure, was that as  $n$  increases the relationship between connectance and stability changes from (for  $n=4$ ) a smooth falling away of probability of stability as connectance increases towards a step function for values of  $n$  of 10 or more. Their figure (partly replicated by the thin lines in Figure 1 here) suggests that for  $n=10$  this phase transition from “almost certainly stable” to “almost certainly unstable” occurs at or around a connected value of 13%,  $C=0.13$ .

Figure 1: Thick lines give the correct results for G&A’s examples, for  $n = 10, 7, 4$  from left to right. Diagonal terms  $a_{ii}$  drawn from  $[-0.1, -1.0]$ ; a proportion  $C$  of off-diagonal terms  $a_{ji}$  ( $i \neq j$ ) drawn from  $[-1.0, 1.0]$ , with the remainder zero. Thin lines copy the incorrect results that G&A showed for  $n = 10, 7$  (Gardner and Ashby, 1970).

## The Programming Error

When we replicated their method<sup>1</sup> our results were similar for  $n=4$ , but noticeably different for  $n=7$  or 10. The difference, shown in Figure 1, is striking, and in particular eliminates the sharp nature of the phase transition claimed for  $n=10$ . This was their main result, and May claimed on the basis of his analytical treatment (May, 1972) to have corroborated this: “The sharp transition from stability to instability, which was the essential feature of their [G&A] paper is confirmed”. Having failed to replicate this sharp transition, the first step was to check whether we had misinterpreted their methods. But eventually a colleague discovered a rarely cited 1999 reference (Solow et al., 1999) pointing out the same problem, with results agreeing with our own presented here. They attributed the problem to some unknown programming error in G&A’s code. Further, they comment that this nullifies one of May’s conclusions where he had assumed that the G&A phase transition was a real phenomenon. Correction of this programming error does not alter the conclusion that as  $n$  increases and  $C$  increases the probability of stability goes down; it does alter the conclusion that for values of  $n$  above some fairly small value the relationship between stability and connectance turns into something close to a step function.

For the purposes of this paper, this programming error is the least important of the errors and omissions to be discussed. Nevertheless, it is of note that it took nearly 30 years until this error was pointed out in print.

## May’s analysis: linear systems

Whereas G&A explicitly limited themselves to the consideration of linear systems “merely as a first step towards a more general treatment” (Gardner and Ashby, 1970), May claims to be considering systems “which in general may obey some quite nonlinear set of first-order differential equations.” (May, 1972). His method is to focus on the behaviour of such nonlinear equations around “the equilibrium point”. Through making a Taylor expansion and ignoring the higher-order terms one can consider this locally as a linear system. Thereafter, May goes on to analyse the same kind of linear system as G&A, while still claiming that it generalises to nonlinear systems.

Insofar as May’s analysis is restricted to the linear version, he tackled analytically much the same class of systems that G&A had tackled computationally. To be precise, this was a slight variant with qualitatively the same behaviour; in place of just  $C$  or connectance he considers a term  $\alpha$  that is the mean square value of the distribution of all off-diagonal elements, described as expressing the average interaction “strength” (measured on a scale that rates the negative self-feedbacks on the diagonal of the matrix at -1). May’s results were broadly similar, claiming that the central feature of the results for large systems is “the very sharp transition” from stable to unstable behaviour above a critical value that “accords with Gardner and Ashby’s conjecture”. As we have pointed out above, in fact the transition is not as sharp as

G&A indicated; however the analytical results do agree with a correctly coded computational Monte Carlo approach. The influential take-home message from both the computational and analytical results has been: in any such system of many interacting parts, as soon as the average interaction strength (interactions between different component parts) rises above some small value, the probability that such a system will be stable drops to near zero. This limitation on stability becomes worse as  $n$ , the number of parts, increases. In the context of ecosystems, such a result challenges the commonly held assumption that the more diverse an ecosystem is, the better it is able to remain stable in the face of perturbations.

## Picturing Stability

In preparation for understanding nonlinear systems, we first present in some detail a sketch of how to analyse and visualise stability in linear systems. This is basic textbook material, but that is the level of the flaws that we are going to exhibit when we move on later to nonlinear systems. For a simple system of two variables, we can graphically sketch the nullclines (where  $dx/dt=0$  and  $dy/dt=0$ ) and, by plotting the consequences of perturbations, analyse for stability. We start with two linear examples, Equations 2 and 3, sketched and analysed in Figures 2 and 3:

$$\frac{dx}{dt} = -x + \frac{y}{2} + 1 \quad \frac{dy}{dt} = \frac{x}{2} - y + 1 \quad \text{Eqns 2}$$

$$\begin{pmatrix} -1 & 0.5 \\ 0.5 & -1 \end{pmatrix}$$

Figure 2: The nullclines for Eqns 2. Thick line for  $dx/dt=0$ , with horizontal small arrows indicating responses to  $x$ -perturbations. Thin line for  $dy/dt=0$ , with vertical small arrows for response to  $y$ -perturbations. The heavy arrows sum these responses, giving a stable equilibrium at the intersection (2,2).

<sup>1</sup> Matlab code at [www.informatics.sussex.ac.uk/users/inmanh/stable](http://www.informatics.sussex.ac.uk/users/inmanh/stable)

The Jacobian matrix restates the fact that the self-connections are -1, and the cross-interactions are 0.5. These latter correspond to  $\tan(X\text{-slope})$  and  $\tan(Y\text{-slope})$  as those angles are indicated in the figure. In contrast, consider this example with the same nullclines, though swapped around:

$$\begin{aligned} \frac{dx}{dt} &= -x + 2y - 2 & \frac{dy}{dt} &= 2x - y - 2 & \text{Eqns 3} \\ & \begin{pmatrix} -1 & 2 \\ 2 & -1 \end{pmatrix} \end{aligned}$$

Figure 3: Nullclines for Eqns 3. Thick line ( $dx/dt=0$ ) has now swapped places with thin line ( $dy/dt=0$ ). Response arrows also differ from Figure 2, equilibrium at (2,2) is now unstable.

Here we can see that the equilibrium is unstable. We can note that the connection strengths, the off-diagonal terms in the matrix, also here  $\tan(X\text{-slope})$  and  $\tan(Y\text{-slope})$ , are now 2 rather than 0.5. So anecdotally this conforms to a general picture that larger connection strengths are more conducive to instability; though we should also note that if these connection strengths had been of opposite sign, of whatever strength, stability would have been the consequence. We can now see how this analysis extends to the nonlinear picture.

### May's analysis: nonlinear systems

May (1972) does not lay down any constraints on the very general class of nonlinear systems, bar implicitly that they should be smooth and differentiable so that they can be approximated by a linear system around any equilibrium point under investigation. For simplicity we start by restricting ourselves to systems of the form:

$$\frac{dx_i}{dt} = \sum_j F_{ji}(x_j) \quad \text{Eqns 4}$$

and further restrict the classes of functions to just linear and sigmoid. We can demonstrate our essential points with a two-variable system:

$$\frac{dx}{dt} = -x + y \quad \frac{dy}{dt} = \frac{20}{(1 + e^{(10-x)})} \quad \text{Eqns 5}$$

The numbers have been chosen to demonstrate that there are now several equilibria, as demonstrated by the intersection of nullclines in Figure 4. We can see that two of these equilibria conform to the pattern of Figure 2 (and are stable), whereas the central equilibrium conforms to the pattern of Figure 3 (and is unstable).

Figure 4: Nullclines for Eqns 5. Three equilibria are circled, the central one (open circle) is unstable, the other two (closed circles) are stable.

### Which Distribution of Connection Strengths?

With the aid of this sketch we can make the trivial observations that the addition of even a single simple monotonic nonlinear function, such as this sigmoid, means that there can be several equilibrium points and that in general the slope of the nonlinear function, related to connection strength, varies from one equilibrium to another.

May wishes to extend the conclusions of the linear analysis – where the probability of stability depends on the nature of the distribution from which connection strengths are drawn – to a nonlinear case with an undefined distribution of nonlinear functions. But this could only be done systematically by firstly specifying the distribution of parameters in the specified class or ensemble of nonlinear functions; and secondly, determining where on such functions one measures the slope. Since there can be several equilibria, this gives several possible values for the connection strength. Given that low connection strengths tend to be conducive to stability in the linear case, it can be noted that many nonlinear functions including these sigmoids have regions where the slope is low.

May would need to do all this to complete his project of generalizing to nonlinear systems. One could then in principle find the distribution of connection strengths over all the equilibria, and perhaps give an estimate of the proportions of these that were stable or unstable. But then further work would need to be done to assess whether the system as a whole was stable or not, since that is a global property.

## Global versus Local Stability

For a system to be globally unstable, every single equilibrium point must be unstable. But for stability it is sufficient for there to be just a single stable equilibrium point within the region of interest. In the case of linear systems, global stability and local stability are one and the same, but May's analysis fails to take account of the fact that nonlinear systems are different. Even if we had an estimate of the probability of any specific equilibrium point being stable, this may well be a gross under-estimate of the chance of there being stability somewhere within the system as a whole.

In some classes of nonlinear functions, e.g. sinusoidal, there is the potential for an unlimited number of intersections with a straight line, corresponding to an unbounded number of equilibria in the two-variable system. For well-behaved curves, as we can see in Figure 4, stable and unstable equilibria alternate so that as long as we have more than one equilibrium we are guaranteed a stable one.

For simplicity, in order to get the main points across, the examples above are restricted to systems of just two variables. Extending this to an  $n$ -variable system with  $n > 2$  requires more analysis. But in summary, the May analysis simply ignores these crucial differences between nonlinear and linear systems, and in doing so typically underestimates, perhaps grossly, the probability of stability in nonlinear systems.

## Ambiguous Circuits

Thomas and colleagues (Thomas and D'Ari, 1990; Thomas and Kaufman, 2001a, 2001b) discuss the roles of positive and negative feedback in nonlinear biological systems. It so happens that their main interest is in the positive feedback circuits that lead to multistationarity, or switching, in genetic regulatory circuits. Nevertheless, much of their analysis can be applied to investigating issues of negative feedback circuits leading to homeostasis or stability. As with May, they are considering a dynamic system of  $n$  variables where many (but typically not all) pairwise interactions are present. This leads to the same connectance or Jacobian matrix. But unlike May they explicitly note that in the general nonlinear case the strengths (and indeed possibly the signs) of these interactions will vary throughout phase space.

Following their analysis, we note that any connectance matrix  $A$  can be considered as composed of multiple overlapping feedback circuits. For any such circuit, the indices are circular permutations of each other. For instance in a 3-variable system as sketched in Figure 5, the full list of potential circuits is:  $\langle a_{11} \rangle$ ,  $\langle a_{22} \rangle$ ,  $\langle a_{33} \rangle$ ,  $\langle a_{12}a_{21} \rangle$ ,  $\langle a_{23}a_{32} \rangle$ ,  $\langle a_{31}a_{13} \rangle$ ,  $\langle a_{12}a_{23}a_{31} \rangle$ ,  $\langle a_{21}a_{13}a_{32} \rangle$ . If one or more of the connections in such a circuit is zero, that circuit as a whole is non-functional; but otherwise, a count-up of the number of negative connection weights decides whether that individual feedback circuit constitutes a negative feedback (odd number of negatives) or positive feedback (even number). The limiting case of such a circuit is that constituted by self-feedback, given by the term  $a_{ii}$  on the main diagonal; that minimal circuit will be non-functional, negative-feedback or positive-feedback depending on whether its value is zero, or its sign is negative or positive.

Thomas and Kaufman (2001a) defined a full-circuit as those circuits and unions of disjoint circuits that involve all the variables of a system. Hence in this 3-variable system, there are six possible full-circuits:

$$\langle a_{11} \cdot a_{22} \cdot a_{33} \rangle, \quad \langle a_{11} \cdot a_{23}a_{32} \rangle, \quad \langle a_{22} \cdot a_{31}a_{13} \rangle, \quad \langle a_{33} \cdot a_{12}a_{21} \rangle, \\ \langle a_{12}a_{23}a_{31} \rangle, \quad \langle a_{13}a_{32}a_{21} \rangle$$

Figure 5: The eight potential circuits, differentiated by shading, within a system of 3 variables fully interconnected.

These correspond to the terms of the determinant of the Jacobian matrix. For any one such full-circuit, considered in isolation, the type of steady state this generates will be determined entirely by the signs, plus or minus, of the various component circuits that comprise this full-circuit. Given that in nonlinear systems any (or all) connection strengths can vary according to position in phase space, and given that the change of sign of any one connection will change the sign of any component circuit of which it is part, we can see that this will alter the type of steady state generated.

This highlights the significance of those connection strengths in a nonlinear system that change in sign as one moves through phase space. These arise from nonmonotonic functions that generate circuits that switch between negative and positive according to context – ‘ambiguous’ circuits – and thereby generate ambiguous full-circuits. Such changes in sign, in one or many such connections, carve up the phase space into different regions, and one can expect the properties of steady states to differ from one such region to the next. This gives the richness of possibilities to nonlinear systems that is missing from the linear ones.

## Plausible nonlinearities

It might be argued that with some systems, although interactions are potentially nonlinear they are ‘linear enough’ for there to be only a single equilibrium. Here we present and discuss some simple nonlinear functions, to see where and how they generate multiple possible equilibria. If one was to analyse fully the probability of stability in some class of nonlinear systems, these might be appropriate simple classes to start on.

## Sigmoids

Sigmoids are commonly used to model physical or biological systems, since they represent an effect that is monotonic yet with asymptotes at lower and upper bounds. A widespread example of where they are used in artificial systems would be Artificial Neural Networks. We have already seen above (Equations 5) that even a simple monotonic function such as a sigmoid is not 'linear enough' to avoid multiple equilibria. The ambiguous circuits discussed above, generating changes in stability through nonmonotonic functions, do not exhaust the ways in which multiple equilibria can exist. Figure 4 demonstrates how both stable and unstable equilibria can be generated merely by a change in strength of a connection without change in sign.

## Piecewise linear with a single bend

Even simpler than a sigmoid, consider a piecewise linear function coupled with a linear function:

$$\frac{dx}{dt} = \max(0, 2 + y - 2x) \quad \frac{dy}{dt} = x - y \quad \text{Eqns 6}$$

These are both linear except that  $dx/dt$  is constrained not to go below zero. As can be seen from Figure 6, this is sufficient to generate a pair of equilibria, one stable and the other unstable.

Figure 6: A perturbation analysis of Equations 6, using the same conventions as in Figure 4. There is a stable equilibrium at (2,2) and an unstable equilibrium at the origin (0,0).

## Sinusoidal functions

We have seen how the single inflexion of a sigmoid allows the possibility of 3 intersections with a straight line and hence 3 equilibria. Crudely speaking, the more bends the more possibilities for intersections, and with oscillatory functions such as a sine wave the slope changes in sign repeatedly and indefinitely. The combination of a straight line and a sine wave can lead to an arbitrary number of equilibria that will alternate between stable and unstable. Going further, it can be shown (Kaufman and Thomas, 2002) that a system of 3 variables:

$$\begin{aligned} \frac{dx}{dt} &= -bx + \sin(y) & \frac{dy}{dt} &= -by + \sin(z) \\ \frac{dz}{dt} &= -bz + \sin(x) \end{aligned} \quad \text{Eqns 7}$$

can, depending on the parameter  $b$ , move from having a single steady state for  $b > 1$ , through multiple steady states as  $b$  decreases, with the number of steady states tending to infinity as  $b \rightarrow 0$ . The dynamics change from simple to chaotic, with periodic or multi-periodic windows. The many changes of sign within the regions where nullclines intersect provide ambiguous circuits and increase the richness of possibilities.

## Hat-shaped functions

Figure 7: Three 'hat-functions' with broadly similar consequences: gaussian, truncated parabola, and witches hat.

Unimodal 'hat-shaped' functions whose slopes have a single change of sign are an important class of simple nonlinear functions that share some of the asymptotic properties of sigmoids. The examples in Figure 7 share the property of dropping to zero (or approaching zero in the case of a gaussian) each side of a central region. If we take any of these hat-functions as  $y=H(x)$ , this could represent a viability function of an organism or species  $y$  that can only survive (in the case of the gaussian version: survive to any significant level) within some range of values of an environmental variable bounded above and below. These can be considered amongst the most basic of nonmonotonic functions, and it turns out that they do indeed play a crucial role in giving rise to homeostasis, or a particular form of stable equilibrium, in Daisyworld models. Those who use Daisyworld models (which are one class of nonlinear complex system) assert that homeostasis arises naturally in these, whereas many critics such as Kirchner (2002) consider the probability to be vanishingly small unless the parameters are fixed somehow. This controversy illustrates some of the archetypal contrasting viewpoints presented in the complexity-stability debate, and hence we shall review this at greater length.

## Daisyworld

Lovelock introduced the Daisyworld model (Watson and Lovelock, 1983) as a possible explanation of how organisms coupled in mutual feedback with some environmental variable could form a homeostatic system, biotic-environmental, as is proposed in the Gaia Hypothesis (Lovelock, 1972). The Faint young Sun paradox (Sagan and Mullen, 1972) suggests that despite the heat output of the sun changing significantly over the last few billion years the planetary climate has maintained itself around the temperatures conducive for life. The Gaia Hypothesis suggests that this arises through homeostatic properties of the interactions between biota and environment. In the Daisyworld model the organisms (Daisies) have a viability whose dependence on temperature is given by a hat-

function; the truncated parabola version is used in Watson and Lovelock (1983). In turn, through differential absorption or reflection of sunlight, these Black or White Daisies had a positive or negative affect on the same local temperature that influenced their viability. Such systems can be analysed for stability in the context of noise or perturbations at two levels.

In the first instance, any equilibrium state of such a system can be analysed for stability or instability in the presence of small levels of noise; only stable equilibria will persist, and only stable equilibria that have the biota (Daisies) within their viability zone are relevant. But the main interest of Daisyworld models is the extent to which such stable equilibria can persist in the face of major systemic external perturbations, such as major changes in heat output of the sun. It turns out that the Daisyworld temperature is maintained within the viability zone for significantly greater ranges of solar forcing *with* the biotic feedback to the local temperature, as compared to *without* such feedback. This homeostasis arises from the nonmonotonic nature of the hat-function.

Figure 8: The witches hat-function represents the dependency of Black Daisies on local temperature.

Harvey (2004) showed how a simplification of the Daisyworld model produced the same effects, using a witches hat-function. A reduced version of such homeostasis can be shown with just one species of Daisies, e.g. Black ones. With  $Y$  black daisies, local temperature  $T$ , level of solar forcing  $S$ , then for suitable constants  $k_1$   $k_2$  we have:

$$\frac{dY}{dt} = H(T) - Y \quad \frac{dT}{dt} = S - k_1 T + k_2 Y \quad \text{Eqns 8}$$

The equilibria are shown where the corresponding lines intersect in Figure 8. The different sloping lines, intersecting the temperature axis at A1, A, A2, correspond to different possible levels of solar forcing. It can be seen that, depending on the level of solar forcing, there is either one equilibrium (e.g. at A1 or lower temperatures, or at A2 and higher temperatures) or three (e.g. A, B, C). This latter case gives us: a possible stable equilibrium with zero Daisies at A; or an unstable equilibrium with Daisies at B, the instability being despite the temperature being viable; or a further stable equilibrium at C with Daisies present within their temperature viability-zone. This last stable equilibrium is the focus of interest, and we consider the range of solar forcing for which C exists; i.e., for which there is a stable population of Daisies within the local temperature viability zone. From inspection of Figure 8 we can see that the biotic feedback (from Black

Daisies increasing local temperature) has given rise to viable local temperature over a wider range of solar forcing (corresponding to the range A1↔A2 in the figure) than in the absence of such feedback (corresponding to D↔A2, the unassisted viability range of the hat-function).

Thus the presence of Black Daisies extends the range of viability towards lower solar forcing (the 'faint young sun'); conversely, White Daisies (giving rise to a line ABC with a negative slope in contrast to the positive slope in Figure 8) would extend the range of viability towards higher solar forcing, a hotter sun. This increased range of homeostasis arises from the nonmonotonic nature of the hat-function generating extra possible equilibria.

### Criticism of Daisyworld

This present analysis of the G&A and May papers was originally motivated by work on Daisyworld models (Harvey, 2004) that are one class of these nonlinear systems of a Gaian biota/environment. Such models display homeostasis under a wide range of conditions, yet critics frequently voice the suspicion that this must be because the parameters are carefully chosen from an improbable subset, biased towards negative feedback, in order to achieve stability. For instance Kirchner (2002) suggests that Gaian regulation depends on an implausible assumption that the influence of biota on the environment have a strong tendency to be environment-enhancing rather than environment-degrading. This, it is implied, suggests that such influence has been biased by the modeler to have the appropriate sign, positive or negative. Yet, as is shown in Harvey (2004), regardless of the sign of such a biota→environment effect, when combined with a hat-shaped viability function environment→biota, the resulting ambiguous circuit has the potential for both stable and unstable equilibria within the viability range. Stable equilibria will inevitably be 'selected' in preference to unstable, but since this is independent of the sign of the biota→environment effect it cannot be attributed to some biased choice of this sign. In either case the viable stable equilibrium gives a context that defines this effect as locally environment-enhancing.

This has inevitably been a limited review of the basics of Daisyworld models, missing out many layers of subtlety. For instance the role of hysteresis has not been mentioned, and the significance of those stable equilibria that are within the viability zone, as contrasted with stable equilibria corresponding to extinction, has been treated only briefly. But the main point to be emphasised here is that the interesting (and often counter-intuitive) properties of these models arise from exactly those features of nonlinear systems that May had omitted in his analysis.

Importantly in this context, the homeostasis of Daisyworld systems extends to those with large numbers of variables. Applying these lessons to the construction of artificial systems, it has been demonstrated (Harvey, 2004) that a simulated robot coupled with the environment via an arbitrarily large number of interactions comprising hat-functions (on sensory inputs) and linear functions (on consequent outputs) could find a homeostatic equilibrium. This is so even if the signs of the linear functions are set positively or negatively at random, and the relevant

parameters are varied across some two orders of magnitude. Other examples of systems with multiple interacting component parts achieving equilibrium through the use of hat-functions can be found in Dyke et al. (2007) and McDonald-Gibson et al. (2008). In these cases there was a single environmental variable, and numerous biotic variables subject to hat-function viability limits. The Daisystat (Dyke, 2010) extends this approach to multiple environmental variables.

## Conclusions

The core of this paper is the demonstration that May's (1972) generalization to nonlinear systems – of results that largely hold true in linear systems (Gardner and Ashby, 1970) – is flawed. The method, through linearization around an assumed single equilibrium point, will at best give local stability; there may be many equilibria, and global stability can arise through stability at just one of these. With nonlinear interactions the size, and potentially also the sign, of the connection strengths varies according to position in phase space, and there is no attempt to account for this. To be rigorous, the probability of global stability would depend on assessing the (differing) probabilities of local equilibria, and combining these to calculate the probability that at least one was stable. No attempt at this was presented in (May, 1972), and hence his conclusions should be rejected. His calculations underestimate, potentially by a massive factor, the probability of stability in systems “which in general may obey some quite nonlinear set of first-order differential equations”.

The ambiguous circuits proposed by Thomas and colleagues in their analysis of multistationarity have been used above to explain how a plurality of equilibria can be generated by nonmonotonic functions. But even simple monotonic functions such as a sigmoid can generate alternating stable and unstable equilibria. A number of different simple nonlinear functions were analysed, to demonstrate just how easy it is to breach the assumptions upon which May was relying.

## Does this matter?

Daisyworld models, particularly as the number of variables increase, are just one example of a complex nonlinear system where one would expect May's analysis to be relevant. These demonstrate typical properties of many families of complex nonlinear systems: if one treats the slower variables as parameters and the faster variables as thermal noise, then the remaining variables at intermediate timescales will settle down to a metastable equilibrium (that may be disturbed at a ‘tipping point’ when a ‘parameter’ shifts enough). In ecology it used to be a common view that ecosystems developed through succession towards a single equilibrium state or ‘climax’ (Clements, 1916); but nowadays ecologists are more open to the possible of multiple possible equilibria in an ecosystem.

Our intuitions based on understanding simple linear systems can all too easily lead us into error when considering complex nonlinear ones, with multiple overlapping circuits of feedback. This appears to be the root of the problem here. We are not aware of any previous exposure of these flaws in May (1972); indeed the author is still citing it without qualification

(Haldane and May, 2011) in the context of ‘banking ecosystems’ where clearly there are nonlinearities. It took nearly 30 years for the basic programming errors in G&A to be pointed out in print, and 40 years is too long for these further significant flaws to remain unchallenged.

## Acknowledgments

I thank Nathaniel Virgo and David Waxman for discussions, and for checking that my code was working properly when it failed to replicate G&A. NV found the prior reference to this anomaly (Solow et al., 1999). Anonymous reviewers' comments stimulated the expansion and clarification of some sections; remaining errors and obscurities are the writer's.

## Abstract

We present the Bondable Cellular Automata model, which uses simple 1-dimensional, binary cellular automata as the base atomic elements of an artificial chemistry. Reactions are dependent upon an emergent, 'resolution independent' observable, measurable for individual or composite cellular automata structures. We discuss the rationale behind our choice of observable, 'mean polarity', and behind the choice of a bonding mechanism based on this observable. From simple experimentation we observe that using cellular automata as the underlying dynamical system coupled with mean polarity as the reaction success criterion shows potential to support sustainable emergent behaviour.

## Introduction

The general model for an artificial chemistry consists of the {S (material), R (reaction rule set), A (algorithm)} triplet, with R applied to S according to A (Dittrich et al, 2001). Typically R is hand-coded and applies to a single level of structural hierarchy, while S is composed of atomic types with little or no internal dynamic. This provides ease of analysis at the expense of flexibility.

This work applies a recent, alternate approach of 'sub-symbolic' artificial chemistry, described in RBN-World (Faulconbridge et al, 2009), and in (Faulconbridge et al, 2010), where reactions can apply at any level, with reaction success based upon an internal dynamic of colliding bodies.

Here cellular automata (CA) are used to provide the internal dynamic. By using CA as base atoms it is possible to construct 'Bondable CA' (BCA) systems where the application of R is dependent upon an emergent, possibly 'resolution independent' observable of individual (atomic) or composite (molecular) CA structures. The bonded CA within composite structures are able to exchange state information, introducing new dynamics to the CA, and potentially leading to emergent behaviour and structure in the chemical system.

## Why use Internal Dynamics?

If we allow each body (be it an atom or composite molecule) in an artificial chemistry to possess an internal dynamical system, then we can allow the reactions which occur between bodies to affect the configuration of their systems. Moreover we can allow the reverse: for the configuration of the bodies' systems to affect their ability to react. This way a feedback loop is formed.

This can be achieved by forming reaction rules that are based upon the value of an observable of each body's internal dynamical system. If the chosen observable is measurable for any body of any internal structure or size, be it a single atom or complex molecule, then potentially any two bodies can react with each other, even if their size and structure differ. This allows composite bodies of arbitrary size and structure to be constructed, and allows their dynamical systems to couple and interact. As they grow these composite bodies will take the form of an increasing hierarchy of systems within systems within systems, all interacting with each other.

Further, in the BCA model we have chosen to use an observable that reflects change in the configuration of a body's dynamical system as it occurs, whether or not this change has been caused by reaction with another body. So two bodies that meet the criterion to react with each other at one instance in time might not do so at another instance because of interim change in the values of each body's observable; and vice versa. Similarly, when two bodies react to form a larger, single body, the interaction between their dynamical systems will cause changes to each over time, and might lead to structural instability. If, according to the values of their observables, subcomponents of the single body no longer meet the criterion to remain bonded then decomposition of the single body will occur. Such decomposition will have a knock-on effect upon the internal dynamic of the remaining body, which in turn may cause further, future decomposition, and so on. Thus we have introduced an element of spontaneity to the reactions that take place, allowing them to occur well after or even in the absence of collision between bodies.

So using bodies that possess internal dynamical systems and basing reaction rules upon a suitable observable of those systems allow a rich set of reaction types to take place, between bodies unbounded by size, thus providing a sophisticated platform upon which we can model and explore multi-layered dynamical systems and how they interact.

## Why use Cellular Automata?

The Cellular Automaton is an ideal underlying system for a sub-symbolic chemistry. A tenet of artificial life research is that complex, interesting behaviour may arise from a deceptively simple mechanism, and the cellular automaton is a deceptively simple dynamical system; deceptive because intuition would suggest that from simple rules must emerge simple outcomes. Yet we knew in 1966 that CA with large, intricately constructed transition rules were capable of

universal computation (von Neumann, 1966), and we know now that 1-dimensional CA are capable of performing universal computation (Cook, 2004), or of generating pseudo-random numbers that pass all current tests for randomness (Wolfram, 2002). It is even speculated that CA-type processes are at work in nature, such as the colour patterns generated in the spiral of the Cone Snail, or in the formation of snowflakes (Wolfram, 2002).

Further, a strand of research that allows the CA's transition rule to be altered during iteration has allowed computations to be performed that are not possible with 'simple', standard 1-dimensional CA (Mitchell et al, 1993, 1997), (Kanoh and Wu, 2003), as opposed to those CA which require a partition of cells to store the 'program' to be executed, such as (Cook, 2004). Other work has explored the capability of 2-dimensional CA to perform computations, including universal computation (Sapin et al, 2007).

Thus simple CA, when allowed to interact, have the potential to produce a wider range of behaviours than in isolation. Placing them within the framework of an artificial chemistry, with the continual 'composition, decomposition, re-composition' processes of combinations of CA, allows this potential to be explored in a more open-ended, emergent manner. Figure 1 shows how linking two circular, 1-dimensional CA between just one cell of each can lead to large changes in configuration within a short time, and in automaton B's case interferes with its otherwise short and simple cycle of just 8 configurations.

Figure 1: The impact of linking two circular, 1-dimensional cellular automata between one cell of each. The linked cells see each other's neighbourhood when updating. Note that the simple, cyclic configuration of unlinked automaton B becomes disturbed through interaction, and that both CAs' configurations are affected.

This paper describes the BCA model from different perspectives: from the perspective of the individual CA cells, from the perspective of the CA, the *atom*, and from the perspective of the *molecules*, composed of many CA. It describes the *reaction mechanism* that allows composition, or *bonding*, and decomposition, or *unbonding*, to occur between *bodies*, be they atoms or molecules. It provides an example of collision leading to bonding then subsequent, spontaneous decomposition. It describes and discusses the reasoning

behind and the impact of using *mean polarity* as the underlying observable upon which reactions are based. Finally conclusions are drawn, which will steer the direction of future work.

## The BCA Model

The Bondable Cellular Automata model is an artificial chemistry that uses 1-dimensional, binary CA for its base (atomic) elements. These atoms bond to form molecules and molecules further bond to form larger molecules of arbitrary size. Adopting the approach in (Faulconbridge et al, 2009), the reaction rules between bodies (whether they be singular atoms or composite molecules) are not explicitly defined for each type of body, but instead reaction success is based upon the comparison of the value of a single observable for each body; an observable that is based upon the internal CA configurations yet can be measured for any constructible body.

### Model Perspectives

Since BCA is an artificial chemistry based upon cellular automata it is useful to describe and observe it from different perspectives.

**Sub-atomic Level.** BCA can be viewed as a collection of interacting cells. Each cell updates its binary state each iteration, according to the collective state of its perceived neighbourhood of other cells and its assigned transition rule. Figure 2 illustrates the cell's perspective.

Figure 2: The central (green) cell perceives its neighbourhood as its left and right neighbours, which for rule-width 2 is the 2 cells either side (in blue), but BCA allows a cell to perceive the neighbourhood of a cell in another CA, allowing information to flow between them.

**Atomic Level.** BCA can be viewed as a collection of bondable atoms. Each atom is a circular CA and bonding causes cells in one atom to link to cells in another atom, as shown in Figure 3. Atoms with positive polarity can bond to atoms with negative polarity while atoms with the same polarity cannot bond and atoms with zero polarity are always inert; this is the 'bonding criterion'. At any instant in time an atom's *polarity* is defined as:

$$\text{polarity} = \text{count}(\text{cells in state '1'}) - \text{count}(\text{cells in state '0'})$$

So, in Figure 3 the upper atom has 5 cells in state '1' and 7 cells in state '0', giving it a polarity of  $5 - 7 = -2$  (polarity sign: *negative*). Similarly the lower atom has polarity of  $12 - 0 = +12$  (polarity sign: *positive*). Hence these atoms can bond.

Figure 3: Two bonded atoms are linked between pairs of cells (colour-coded accordingly). Each cell sees its partner's neighbourhood when updating.

Bonding causes cells in one atom to link to cells in the other atoms. Cells can have only one link at a time. Linking causes a cell to view the corresponding cell's neighbourhood rather than its own when updating. Atoms can be bonded to many other atoms, limited only by the availability of unlinked cells. This leads to a rich, complete-graph structure for bonded atoms, as illustrated in Figure 4.

Figure 4: The underlying atomic structure of a molecule. Each atom is a circular CA, and each CA has its own transition rule.

**Molecular Level.** BCA can be viewed as an artificial chemistry, a collection of molecules that collide in pairs and bond.

Due to two body reactions each molecule consists of exactly two (sub) molecules or (conceptually) of a single atom. Figure 5 shows how this leads to a binary-tree structure for molecules, with each parent molecule containing two child molecules.

When molecules collide, if they meet the bonding criterion, then they bond. If they bond this may cause changes to the internal configuration of the CA, which in turn affects polarity, which may lead to sub-components unbonding, which is explained later in the Bonding Example section.

Molecules bond by linking pairs of atoms, one in each pair from each molecule, and how these pairs are chosen and linked is described in the next section. A key aspect of BCA is that the rich underlying atomic structure of molecules is hidden at this molecular level. This greatly simplifies the

description of molecular types and reactions. Also it is possible for two molecules with the same molecular identity to have different structure at the atomic level, thus allowing isomers to be modeled. Moreover, since a molecule's polarity is the emergent outcome of initial configuration, the transition rules and the topology of the underlying atomic bonds, it is possible for two molecules of the same type to possess opposing polarities and thus bond.

Figure 5: Molecular structure is nested, forming a binary tree. Key: Molecule (rounded square), Atom (outlined ring).

## Material and Reactions

### Atoms and Molecules

In BCA, 1-dimensional, unbounded (circular) binary CA form the atomic elements, their type identified by their transition rule. Atoms can bond to form molecules, and molecules can bond to atoms or other molecules to form ever-larger molecules.

Single atoms behave like standard CA, updating the state of each cell each iteration according to the application of the transition rule to the cell's neighbourhood.

When two atoms are bonded, pairs of cells between each atom are 'linked' together. When updating, linked cells still use their own transition rule but see their partner's neighbourhood instead of their own. Thus the cell states (the 'configuration') of paired atoms affect each other.

### Collisions

BCA's topology is a well-mixed soup, consisting of *bodies*, which can be single (unbonded) atoms or composite molecules. At any point in time collision can randomly occur between any two bodies. Two bodies that collide are known as the reactants, and are tested to see if they will bond according to the bonding criterion.

### Bonding Criterion

Reactants bond according to the mean polarity of each reactant's configuration.

Reactants with opposing polarity signs may bond (positive-to-negative or negative-to-positive) whilst any reactant with

neutral-signed polarity is considered inert and will not react with any other body.

We note that polarity is a scalable, ‘resolution independent’ observable in our model, since it can be measured for single atoms and for molecules of arbitrary size. Polarity is also an emergent property of the configuration of a body, which itself is an emergent property of the initial configuration and transition rule(s) of the underlying CA, and of the effect of the bonds between them. Hence polarity is an emergent property of the underlying dynamical systems and how they interact.

## Bonding Mechanism

**Atomic Level.** Two atoms with opposing polarities bond by forming links between pairs of cells. Which cells link to form the ‘bond site’ is determined by comparison of each CA’s configuration at the time of collision. In keeping with the concept that ‘opposites attract’, the longest continuous run of currently unlinked state 1 cells is identified in the ‘positive’ atom, and the longest run of currently unlinked state 0 cells is identified in the ‘negative’ atom. The shorter of these runs determines the size of the bond site. Each cell in the shorter run is then linked to a cell in the longer run on a 1-to-1 basis until the shorter run is exhausted. Thus every cell has the potential to contribute to a bond site, and therefore to interact with cells in other CA, while the actual location and size of the bond site is an emergent outcome of the automatas’ current configurations.

**Molecular Level.** When two molecules with opposing polarities collide, they form bonds between pairs of atoms, in the manner described above. The molecules will attempt to form bonds between two pairs of atoms, but in practice might form a bond between only one pair, or even not be able to form any bond at all, as the process below explains.

Each molecule is polled for its atom with most positive polarity, and its atom with most negative polarity. Again, by the principle that opposites attract, the most positive atom in the first molecule is paired with the most negative atom in the second molecule (and respectively for the other pair). These atoms bond together at the atomic level in the manner described in the previous section.

Sometimes the chosen pairs of atoms cannot bond, because one or both atoms has no free, unlinked cells with which to form a bond. In this situation any ‘fully linked’ atom is overlooked and the molecule polled for the next most positive/negative atom as appropriate. This process will continue if necessary until either a bondable pair of atoms is found or no more candidates exist. In the latter situation this will lead to the molecules bonding between just one pair of atoms, or in the extreme case not bonding at all.

Allowing two pairs of atoms to possibly form the bond between molecules maintains consistency with the concept that polarity underpins the bonding mechanism, with the most-oppositely polarised atoms in each molecule being attracted to each other and attempting to bond. The key benefit of allowing more than one pair of atoms to bond between molecules is that it allows a rich graph structure to develop at the atomic level, illustrated in Figure 4. If only one pair of atoms were allowed to bond between molecules then this structure would be restricted to a tree, providing less

opportunity for interaction between the atoms within a molecule.

## Unbonding Mechanism

Unbonding occurs spontaneously at the molecular level. If a body consists of more than a single atom, then every iteration of the system the bonds between the two sub-components that form a body are tested. The test is simple: if the two atoms which are actually bonded no longer attract, then they unbond. Unbonding removes all links between paired cells in each atom, and their CA no longer interact.

This unbonding will weaken the link, and hence interaction, between the two sub-components of the body, and if it was the last bond will lead to separation of the body into smaller bodies. Those bodies will then themselves be subject to potential spontaneous decomposition, and so on.

## Bonding Example

Figure 6 illustrates by example the composition of two colliding molecules, and their subsequent decomposition into two new molecules.

Let A and B be molecules in the BCA system. Further, let A be composed of sub-molecules C and D, since this fact will become useful when describing the decomposition stage.

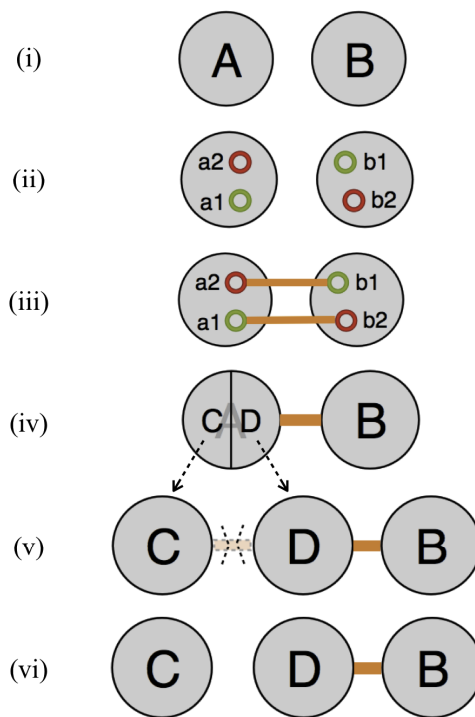

Figure 6: Example of the bonding of two molecules, A and B, and the subsequent, spontaneous decomposition of the resultant into two different molecules, C and D-B.

**Composition.** Suppose that A and B collide (Figure 6.i). They have opposing polarities and attempt to bond.

Let the most positive and most negative atoms in A be identified as a1 & a2 (respectively as b1 & b2 in B; see Figure

6.ii). Unlinked cells are available on each atom and so a1 bonds to b2 while a2 bonds to b1 (Figure 6.iii). The molecular equation for this reaction is simply:

A-B denotes composition. Since the reaction success of A + B is not guaranteed for every collision between the types, the current equation is insufficient. So during simulation our system records the percentage reaction success of collision between pairs of types and we can more accurately write the equation as:

Note that this says nothing about the underlying atomic structure, thus allowing the aforementioned isomers to exist.

**Decomposition.** We now suppose that the formation of A-B leads to changes in the cell states of the underlying CA, through interaction between bonded atoms. These changes subsequently cause the bonded atoms in A's two sub-molecules, C & D (see Figure 6.iv), to no longer attract. Hence the bonds break and A decays (Figure 6.v).

This leads to the breakaway of C as a separate body, while D remains bonded to B, effectively forming a new molecule (Figure 6.vi).

The equation for decomposition is:

$N_i$  represents the number of iterations the composite survived for, and the comma indicates separation. We can consider  $N_i$  as the reaction rate for a decomposing reaction. The full chain of events can be written as:

Some composites will decompose into the original two molecules that formed them, so reversible reactions can be supported by the model.

During the run of a simulation we can track the entire flow of compositions and decompositions for all molecules to derive the reaction network.

## The Impact of Polarity

The choice of polarity as the basis for the bonding criterion followed a process of deduction and experimentation.

Table 1 lists the key, measurable properties of a CA and their suitability for the role. It was quickly identified that any candidate property for underpinning the bonding criterion would need to be not just resolution independent, but would also need to at least in part reflect the dynamic nature of a CA's configuration in order to be an emergent property leading to emergent behaviour.

Therefore rule width, dimension, number of cell states and size were discounted as too trivial to be useful since they remain constant or ignore the CA's configuration; they effectively reduce to static elemental types seen in the general artificial chemistry model. Likewise Transition Rule was

discarded for the above reason and further since it cannot be consistently defined for bonded structures.

	Resolution Independent?	Dynamic?
Rule width	Yes	No
Dimension (1d, 2d, ...)	Yes	No
No. of possible cell states	Yes	No
Size	Yes	Weakly
Transition rule	No	No
Configuration	Yes	Yes

Table 1: Summary of key measurable properties of CA.

This left measures based upon Cell Configuration, which fall into two broad categories: long-term measures and instant measures.

A good example of a long-term measure is cyclelength, as used for RBN-World. We can measure the cyclelength of a CA as the number of iterations required for the configuration to return to a previous state. One strength of using cyclelength is that it is an emergent outcome of bonding; as structures bond the cyclelengths of the sub-components and the combined structure can change. Also, since cyclelength is partly dependent upon other properties of CA such as transition rule and the current configuration, it could provide a valuable reflection of the nature (and specifically Wolfram classes (Wolfram, 1984)) of combined CA.

However one downside to using cyclelength is that its value for a particular body remains static until that body reacts with another body through collision. We believe that using an alternative observable, one whose value can change both because of and independent of reaction with other bodies, adds flexibility to the model since it allows spontaneity and uncertainty to what reactions occur and when.

The other downside to using cyclelength and similar measures is computational cost. Determining the cyclelength of a body in BCA requires direct simulation, since it is dependent upon not just the CA but also how they are bonded; in the worst case its time cost is the Cartesian product of the combined width of a body's CA.

Therefore initially BCA employed the instant measure of polarity at the moment of collision. Instant polarity is an emergent outcome of both internal configuration and the bonding mechanism, is computationally inexpensive (the cost is linear with respect to combined width) and allows for spontaneous unbonding. It also provides underlying consistency to the model: the bonding criterion, the location of bonds in the bonding mechanism (at molecular and atomic levels) and the unbonding mechanism can all be based upon this single characteristic.

Unfortunately during simulation the measure of instant polarity proved to be too stochastic for some transition rules, as Figure 7 demonstrates. The reaction success of colliding bodies became dependent upon the time of collision, which is randomly chosen.

Therefore the measure of mean polarity was implemented. This retains the benefits of instant polarity, including computational cost rising linearly with size, but, as seen in Figure 7, also smoothes the impact of large changes in

configuration between successive iterations. In our experimentation the mean is calculated from the instant that a body is formed, but alternative calculations, such as the mean for the last 100 cycles, could be used, allowing later changes in configuration to have greater impact upon it.

Figure 7: Polarity of a Rule 30 Cellular Automata over time. Whilst the snapshots of polarity change erratically between iterations, mean polarity smoothly settles to a steady value.

## Experiments in Mean Polarity

Rule width	1
Width (number of cells)	12
Dimension	1d
Number of possible cell states	2 (binary)
Number of transition rules	256
Initial configuration of cell states	'000000000001'
<i>Number of iterations:</i>	
Isolated CA	4096
Paired System	100000

Table 2: Set-up for the Isolated and Bonded Pairs experiments.

A key question about mean polarity is whether it would be *too* smooth a measure, essentially reducing in most cases to a static value over time. To answer this question simulations were run using CA with width 12, rule-width 1, providing 256 possible transition rules, or atomic types. Each type of CA was simulated in turn in isolation for 4096 iterations. This is the maximum theoretical cyclelength for a width 12 CA and thus allows a fair calculation of mean polarity over time for the individual CA. Each CA began with the same initial configuration of a single cell set to state '1', all others '0'.

Following this we attempted to bond every possible pair of CA in turn. If they bonded then the simulation was run for a further 10000 iterations, far short of the maximum theoretical 16.7 million iterations required to cover all possible cyclelengths, but in practice sufficient time to determine the long-term sign and magnitude of the pair's mean polarity. Table 2 records the set-up for both experiments. This is the first step into the reaction chemistry of the BCA model.

## Results and Discussion

**Isolated CA.** For 141 out of 256 (56%) of types the sign of mean polarity changes during simulation for isolated atoms. Table 3 shows that although all types begin with negative polarity approximately a quarter of types finish with neutral mean polarity and are hence inert.

Positive	75 (29%)
Negative	115 (45%)
Neutral	66 (26%)

Table 3: Tally of final sign of mean polarity of isolated CA after 4096 iterations.

That such a sizeable proportion of CA types become inert raises concern. However the 'periodic table' of types (Figure 8 in the Appendix) shows that the vast majority of types that achieve neutral mean polarity take more than 256 iterations to do so, and the opportunity for those CA to bond with others and be 'rescued' from inertia remains open during that time.

The periodic table illustrates a strong correlation between the time taken to settle and the amount by which mean polarity changes. All CA begin with mean polarity of -10. Those that finish with that same value never change polarity. Those that finish with mean polarity close to -10 tend to settle within 8 iterations, and as final polarity drifts away from -10, so the time taken to reach the new value tends to increase. We see that many CA types reach high positive polarities, notably acquiring a change of sign, and relatively speaking take their time to do so. This is good since it demonstrates that the mean polarity measure is dynamic in the majority of cases for long enough to present a 'window of opportunity' for different reactions to occur.

## Bonded Pairs.

Total possible unique pairs	32640
Of which bonded	8625 (25%)
<i>Change seen in mean polarity value:</i>	
Individual CA	14049 (81%)
Paired System	7921 (91%)
<i>Change seen in mean polarity sign:</i>	
Individual CA	5799 (34%)
Paired System	3938 (45%)
Both CA and paired system changed polarity	371 (4%)
Both CA changed polarity but paired system did not (the changes 'cancel out')	253 (3%)
One CA's polarity remained stable while the other's and the paired system's changed	402 (5%)

Table 4: Summary Data for the Bonded Pairs experiment.

Table 4 summarises the results of attempting to bond in pairs. The listed percentages for changes seen in polarity are calculated as proportions out of the total number of pairs that succeeded in bonding. We observe that in around 4 out of

every 5 of such cases the act of bonding re-introduces a dynamic element to the value of polarity of the individual CA, and in around 1 out of every 3 cases also leads to a sign change. We also see that in almost half of cases following bonding the paired system's polarity sign changes. This reinforces the view that mean polarity is an emergent outcome of both the underlying CA configurations and the bonding mechanism, not just because it aggregates the values for the subcomponents, but crucially because the subsequent interaction caused by bonding leads to changes in the subcomponents' values themselves.

In the 5% of cases where bonding causes a sign change for one of the CA, if this change were rapid then during a full simulation this would lead to rapid decay of the combined body, releasing both atoms near-instantly back into the soup. This provides the potential for bonding to cause the appearance of unstable molecules, leading to rapid chain reaction; a complement to the slower decay modeled in the unbonding mechanism. In such paired systems, the CA whose sign remains stable is also of interest, since it might have catalytic properties, causing change in the CA it bonds with whilst itself remaining unchanged in polarity sign. Seeking and identifying CA atoms with this property, and possibly even molecules too, is a further step in the research.

Additionally, we observed that bonding causes an overall drift away from neutrality for the bonded pairs, so the act of bonding leaves proportionally fewer inert bodies in the system than if CA were left to iterate in isolation.

These results suggest that rather than locking CA into inert structures with (near) static mean polarity as was feared, bonding could be a self-sustaining process, keeping the system active.

## Conclusion and Future Work

The modeling and polarity experimentation suggest that BCA shows the potential to allow behaviour and structure to be emergent properties of both the bonding mechanism and the underlying CA configurations. More generally it allows us to study the results of the interaction that occurs between simple dynamical systems when they are placed within the framework of an artificial chemistry.

By allowing reactions to occur sometime after or even in absence of a collision BCA is also able to model useful chemical concepts such as variable decay rates, spontaneous reactions derived from internal configuration (rather than due to external trauma), isomers, and catalytic behaviour. Thus we believe that it is a worthy candidate system for the study of emergence.

The experimentation suggests that mean polarity could be an ideal resolution independent observable on which to base reaction success, possibly leading to a positive cycle in system behaviour, where reactions lead to changes in the internal structure of bodies leading to the potential for further reactions. However to assess this further experimentation is needed, including full simulation runs where numerous molecule of many types are present, and are allowed to react to form much larger bodies.

Mean polarity is only one of many possible ways to determine reaction success. Other candidate observables based upon CA configuration exist and can be explored too,

including the possibility of basing reaction success upon a family of measures, or on higher moments. For whichever set of observables we select, we need to strike a balance.

The experimentation using instant polarity has shown that using short-term measures which are based on a computationally inexpensive snapshot of the configuration can lead to essentially stochastic behaviour. Conversely, other long-term measures, such as cyclelength, are less sensitive to short term configuration changes but have increasingly large computational overhead as larger molecules appear, which impinges upon the scalability of experimental simulation. So other candidates will need to be able to display the balance that the use of mean polarity so far achieves, in tempering stochastic influence whilst keeping the computational overhead low.

In the experimentation so far the rate of iteration for the CA has been identical to the rate of iteration for collision. So every time the system performs a collision (or a set of simultaneous collisions) it also updates the configuration of every CA. This need not be so, since we can instead allow the CA to operate in a different time frame and iterate them an arbitrary number of times between each collision.

Further work will examine the reaction networks formed by full simulation of the model, assess the impact of allowing the CA configurations to iterate at a different rate to the collisions and assess the model's viability for application to the modeling of other domains.

## Abstract

We model some of the crucial properties of biological novelty generation, and abstract these out into minimal requirements for an ALife system that exhibits constant novelty generation (open ended evolution) combined with robustness.

The requirements are an embodied genome that supports run-time metaprogramming ('self modifying code'), generation of multiple behaviours expressible as interfaces, and specialisation via (implicit or explicit) removal of interfaces.

The main application of self modifying code to date has been top down, in the branch of Artificial Intelligence concerned with *learning to learn*. However, here we take the bottom up Artificial Life philosophy seriously, and apply the concept to low level behaviours, in order to develop emergent novelty.

## Introduction

It is proving very hard to develop *in silico* ALife systems that exhibit open-ended novelty generation. This may be because many such systems are *closed* in that they often have pre-designed and fixed algorithms, and fixed information representations. The scope for these systems to generate novelty is heavily constrained by these design decisions. This closure is in sharp contrast to biology, where its 'algorithms' and 'representations' are themselves products of the novelty generation processes.

In this paper, we go back to biology, and look at certain aspects of its processes that are key to its power to generate novelty. We use these to develop an open computational novelty generation architecture.

A key source of open-ended biological novelty seems to be the embodiment of the genome in a form that makes it accessible to the other active elements of the system: the DNA can be modified by proteins, changing what future proteins are expressed, and what future modifications occur.

We propose that an analogous approach is needed for open-ended computational innovation. The 'computational DNA' (program code) must be accessible to and modifiable by the active elements (executing program). This can be achieved through *run-time metaprogramming*. (Metaprogramming is when programs manipulate programs; here the

Figure 1: (a) Information flow in the central dogma of molecular biology; (b) control flow in classical computer programs. The vertical alignments indicate rough analogy, discussed later.

Figure 2: Control flow in the cell

manipulator and manipulated are the *same* program, and the manipulations are performed at run-time. This is also known as reflective programming in high level languages, and as self-modifying code in assembly languages.)

## Biological models

### Self-innovation circular architecture

Crick's central dogma of molecular biology, first stated in 1958 [5], has a linear flow of information content (DNA → RNA → protein, figure 1a). This informational statement is often more strongly interpreted to mean a linear *control pathway*, with DNA 'in control' of the system, and no returning control paths. The standard paradigm of computation has an analogous flow of control (source code → loaded code → executing code). The source code is 'in control'; all subsequent events are a direct consequence of this code (figure 1b).

Such linear flow models are a simple way to describe causality in a system. However, the linear flow of *control* in biology is false. Proteins act on the RNA, and both RNA and proteins act on the DNA, controlling what is expressed, and even changing the DNA (figure 2). There is no strict

Figure 3: (a) original RNA-world; (b) RNAs and proteins; (c) today's DNA, RNA and protein world. Solid arrows represent the direction of control flow and effect; dashed line represents a molecular stability spectrum.

linear flow of control; it is a closed loop with all entity types able to affect all other entity types. This circularity of interaction allows the emergent biological properties, including novelty generation.

We propose that an analogous circularity of interaction is needed for computational novelty generation: self-modifying self-producing computer *code*, achieved through *run-time metaprogramming*.

## A history of specialisation

Prebiotically there were molecules. Novelty generation resulted in molecules with additional behaviours: RNA encodes information, and can use that information in two ways, as an active *machine*, or as a passive *template*.

In RNA-world [12, 30], the information-bearing template and the active machinery are the same kind of molecules: RNA. However, these two behaviours require different kinds of properties: information-bearing templates require relative stability, whereas the machinery requires reactivity. Biology's solution was to specialise with two sets of molecules: RNA (mainly) for information, and proteins for reactivity. This specialisation continued until today's situation, with the even more stable DNA providing long-term stability for information storage. (See figure 3.)

## The phenotype of the genome

DNA expresses proteins. DNA is composed of *nucleotide bases*; proteins are composed of *amino acids*. These have different reactivity, yet they interact with each other in a variety of ways, such as chemical binding and topological entwining. In particular, different portions of the DNA are physically inaccessible at different stages of the cell cycle. These interactions are subject to selection pressures (limited by physico-chemical constraints), which has led to the

emergence of important biological properties, such as: mutating at differing rates for different genes; specifying when genes express proteins and at what rates; organising the co-location of genes for particular metabolic pathways. These are components of biological innovation.

Analogous properties are not seen to *emerge* in computer simulations (although they can be explicitly designed in).

In order to build a computational analogue of the relevant biological processes, we need to carefully distinguish the genome and the DNA/RNA: (a) the genome is an *abstraction*, a sequence of codes; (b) the DNA (or RNA, in RNA-world) is a physical molecule, *embodying* the genomic information. A protein is another class of physical molecule, its sequence encoded by the genome, physically expressed from the DNA/RNA. In many models of biological evolution the genome and the DNA/RNA that it represents are taken to be synonymous, and the DNA/RNA is modelled differently from the proteins. In reality, however, the genome is an abstraction, and is a different category from the DNA/RNA molecule that is the physical embodiment of that abstraction. The DNA/RNA is an intrinsic part of the *phenotype* of the organism, of the same category as the proteins. Being embodied, it interacts with, and is acted on by, enzymes and metabolites (though less readily than the other entities in the cell).

This embodiment, which we hypothesise is necessary for biological novelty generation, provides the inspiration for our computational architecture to produce analogous open-ended novelty generation *in silico*.

## Computational analogues

We take this aspect of biology, of circular interaction enabled by an embodied template, as inspiration for the design of a computational form of novelty generation.

We perform the following process [27] (for two related biological systems, RNA-world and DNA-world): we produce a model of the *biological* system; we abstract this into a *conceptual* model of the underlying processes and relationships (not shown here); we *instantiate* the conceptual model in computational terms. We use UML class diagrams to express these models.

## AChems as analogues of RNA-world

We first look at the simpler RNA-world (figure 4a). Physics determines how molecules interact, through features such as molecular folding and binding affinities. The genome is an abstraction of the information in the RNA. The biological RNA is embodied: RNA molecules express and are modified by RNA molecules.

The computational analogy is self-modifying code (figure 4b). The analogue of the (disembodied) genome is the (disembodied) source code. The analogue of the active RNA is the executing code: for the analogy to hold, the executing code must be able to modify its own instructions. The

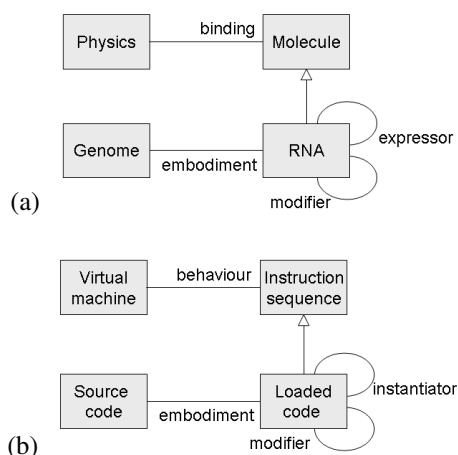

Figure 4: UML class diagram of RNA-world: (a) biological model of embodied RNA; (b) conceptual model instantiated with an AChem

analogue of the physics (which defines how molecules can interact) is the virtual machine (which describes the AChem program language semantics, and how the various AChem objects can interact).

An assembly language level Artificial Chemistry, where the executing code is able to modify the instructions ('embodied source code'), provides a computational model here. Examples include Tierra [26], Avida [1], and stringmol [15, 14, 16], where the 'chemicals' are direct analogues of the RNA strands.

### Reflection as an analogue of DNA-world

Many modern high-level programming languages are designed to enforce a strict separation between code and data, and cannot self-modify in this way. But not all.

We next look at 'DNA-world', a biologically later specialisation of RNA-world (figure 5a). The biological DNA is embodied, and is affected and modified by the proteins it expresses. (Notice this model does not make the biological role of RNA explicit in this process. Here we wish to emphasise the distinction between stable information archive and active machine, so we abstract these as 'DNA' and 'protein' respectively, and omit the intermediate RNA for the purposes of our argument.)

Analogously, the computer source code is *embodied*, and affected and modified by the executing code it specifies (figure 5b). Here we need a programming language where there is a separation between code-representing entities and other active entities (unlike in the RNA/assembly language analogy) that can nevertheless interact at run-time. A high-level language with computational reflection [24] is suitable here: the source code is embodied in the run-time system, and can be modified by the executing system, but is (conceptually) separate from it.

Smalltalk-80 [13] is a good example. In Smalltalk, the

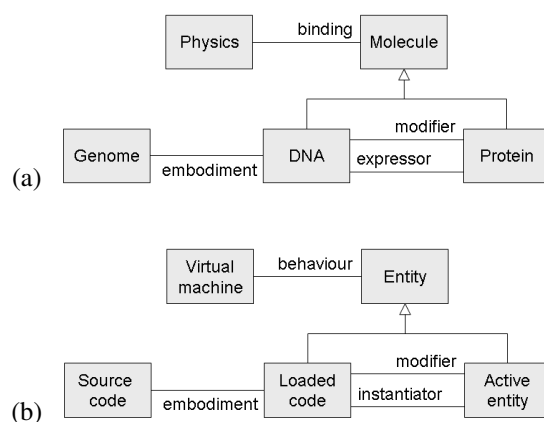

Figure 5: UML class diagram of DNA-world: (a) biological model of embodied DNA and protein machine (omitting the role of RNA, for emphasis); (b) conceptual model instantiated with metaprogramming

Figure 6: UML class diagram of molecules realising (behavioural) interfaces

source code is just another data structure that can be manipulated by the executing program. Smalltalk is a pure object-oriented language: every value is an object, including classes and code blocks. Code blocks, including ones that modify and create classes, can be constructed at run-time and then executed. An executing Smalltalk system thus has the ability to modify and extend itself: its source code is embodied in the executing system.

Other computationally reflective languages (ones that can modify themselves at run-time, to a greater or lesser extent) include Lisp, Prolog, Python, Ruby, and JavaScript.

### Novelty versus specialisation

RNA encodes information, and can use that information in two ways, as a passive *template*, or expressed as an active *machine*. We can model these two different uses in UML as *interfaces* (figure 6). The interfaces capture the specific behaviours exhibited by certain molecules.

Later (in the RNA-world model), *specialisation* occurred. Molecules that had only one of these behaviours, either machine (protein) or template (DNA), emerged. Once specialised components (components that have *lost* an interface) have emerged, they can adapt to perform their specialisation (remaining interface) more effectively. (Biologically,

specialisation to DNA templates and protein machines was mediated by RNA, and there are still RNA molecules that can be interpreted as fragments of this mediation in modern organisms [3].)

So in modelling terms, novelty generation is *creation* of new interfaces, specialisation is *removal* of interfaces from sub-species of agents. In code terms, removal of an explicit interface is simple: it is just deleted. However, removal of an implicit, emergent interface is not so simple: the low-level behaviour has to change such that the interface behaviour no longer emerges. This is the case both in molecular terms, and in low-level AChem systems. In the molecular case discussed here, this process occurred through differentiation into molecules with distinct chemical structures (nucleotide bases in DNA versus amino acids in proteins). This necessitated the introduction of a *decoding* element to the expression relation, to translate from one structure to the other.

We suggest that such a differentiation step will be helpful in any analogous AChem system designed to progress beyond RNA-world level behaviour in this manner. Specialisation of template and machine behaviours requires templates to be less reactive and machines more reactive. Although such differentiation may be achieved in a homogeneous system (for example, by altering ratios of symbols in the underlying alphabet), it is made easier by having some *structural* difference between them, to help this *behavioural* difference emerge. Given a structural difference, translation will be required to take the template into its machine expression. This translation requirement is not inconsistent with template and machinery being the same kind of thing. There is sufficient richness in chemistry to allow DNA and proteins to be the same kind of thing (molecules) whilst having different representations of their information content (nucleotide bases versus amino acids). The similar form of embodiment allows the information to be modifiable by the system it encodes, whilst the different representations provide the separation of properties that help support specialised behaviour. Chemistry is rich enough to provide this spectrum: AChems will need analogous richness.

High level languages can provide explicit support for this process of specialisation. For example, one pattern supported by refactoring tools is *Extract Interface* [11, p.341]. Aspect oriented programming [18] allows particular kinds of behaviour to cut across the code structure. These are both design time, rather than run time, processes, but some of the concepts may be automatable. Another concept, relevant to implicitly-defined interfaces, is duck typing [20], which allows the type to be determined dynamically, based on what methods a class currently supports.

The ‘softness’ in losing (specialising away) an interface is an important property in terms of robustness through redundancy and degeneracy. It is not necessary for a specialist to lose an interface completely, only for the system to lose reliance in it on providing the interface. The specialist

can safely modify other things about itself, but it might still maintain some ability to implement some part of the interface in an ‘emergency’. If enough parts of the system can implement parts of the interface adequately, then this degeneracy amounts to the system as a whole implementing the whole interface. This provides a form of distributed backup, in case of failure of the machine that is ‘supposed’ to implement the interface.

## Computational architecture

The previous discussion leads us to the notion that, to get emergent novelty in simulation, we should look to run-time metaprogramming. In such a system the code has never finished being written, so the program cannot finish running. Open ended computation is obtained, allowing unprescribed novelty generation within the computer. The main application of self modifying code to date has been top down, in the branch of Artificial Intelligence concerned with *learning to learn* [22, 28, 29]. However, here we take the *bottom up* Artificial Life philosophy seriously, and apply the concept to *low level behaviours*, in order to develop emergent novelty.

Run-time metaprogramming on its own is not sufficient; we also need an architecture within which to run the code. The biological models above can help us here, too. There are two aspects to the architecture. One comes from the class box Physics in figures 4a and 5a, one from the roles modifier and expressor.

## Physics engine

Underlying biology there is physics and chemistry: the processes that define how molecules move around, how they can interact (for example, binding affinities), what the result of the reaction is, and the constraints on the system (for example, conservation laws). In an artificial system, we have to explicitly implement analogues of many of these processes. The usual way to do this is in terms of a *virtual machine* (VM), often referred to as a ‘physics engine’, that provides the execution environment in which the molecule-analogues exist. Tierra [26], for example, has an explicit VM that executes the Tierra assembly language.

The first point to note is that physics is **uncrashable**: there is no real world analogue of a computational core dump or fatal exception. There are two ways to achieve this in the computational architecture: language design or VM handling. The molecular language can be designed such that any molecular interaction results in a legal behaviour. This is relatively straightforward at the assembly language level (care still has to be taken not to access areas outside legal memory). Alternatively, the VM can be designed to trap and isolate any unhandled exceptions. For higher level languages that are modifying themselves, this will become the necessary route.

Next, the VM provides the **spatial dynamics**: how the entities move around, and so who can interact with whom.

This can be explicitly spatial, or be a ‘well mixed’ aspatial model, or even a hybrid (a spatial arrangement of containers with aspatial contents, for example).

We want a system that can generate open-ended novelty without dissolving into chaos. A completely unconstrained system could well modify itself out of existence. Some form of constraint might be needed to allow the system to develop in interesting directions without devolving into a mess of molecule soup. However, a completely constrained system, that allows no modification to its architecture and representations, is static and cannot achieve open-ended dynamics. This is the state of most classic agent-based simulations. The VM should provide such constraint through an **energy model**. This is some analogue of the constraints that real-world physics provides, such as conservation of energy. This provides a limited resource for the various entities; in particular, it prevents ‘free copying’, or unlimited replication, and so provides an evolutionary pressure [8, 17]. It is important not to have a ‘closed’ energy system, however: this would lead to equilibrium. Biological systems are far-from-equilibrium systems, maintained there by an energy *flux*. More sophisticated VMs might also provide an analogue of entropy.

It seems plausible that some degree of constraint between a totally static model, and total freedom, is required; this is possibly some *edge of chaos* [21] requirement. Hence the role of the constraint is to help the system self-organise to maximally complex patterns of structure and behaviour.

Some choices of what goes in the VM and what goes in the molecular language are design decisions. For example, it can be beneficial if the entities have a limited lifetime: this results in entities having to renew themselves to survive, which imposes a natural evolutionary pressure on the system. Whether such a **decay** process is implemented in the VM or in the entities themselves is a design decision: the choice will determine how much the decay can be affected by the intrinsic evolutionary process. The presence of such a decay mechanism has consequences. For example, it means that there will need to be multiple copies of certain machine templates (or templates need to have very different decay properties from active machine molecules), so that the decay of a template does not permanently lose a solution.

## Modification and expression machines

The physics engine provides the VM within which entities can interact and generate novelty (novel entities, novel behaviours, novel interactions). We need some initial entities to set the system going.

Consider the roles modifier and expressor in figures 4a and 5a. In biology, these are embodied, ‘implemented’ by specific machine molecules (ribosomes, transposons, chaperone proteins, etc). Additionally, there are machine molecules that do things not related to self-modification: these are the active molecules performing the external ‘func-

tion’ of the system. This provides a route to embedding application-specific behaviours into a novelty generating architecture.

A novelty generating system could be *bootstrapped* with some specialist machines for these various tasks. this involves writing the bootstraps as code for the embodied templates that, when expressed, becomes the active machine. The key point is that these bootstrap machines *are all encoded on the template*, and so are themselves subject to modification, either directly, by a modifier machine changing their encoding, or through imprecise replication by a ‘sloppy’ replicator machine. And these various modification machines are themselves subject to modification. This is why we are describing only the ‘bootstrap’ architecture: the self-modification processes will then develop new machines, new kinds of machines, and new ways of expressing and otherwise generating machines. This self-modification is what breaks away from fixed algorithms and fixed representations, and allows open-ended novelty generation.

Different kinds of bootstrap machines are suggested by different stages of biological evolution. We could bootstrap with only replicator machines (machines that can copy templates). This is the approach we have taken in our original stringmol AChem [14, 15, 16]. Here we wish to short-circuit the process of evolving all novelty from scratch, but in a way that does not compromise further open-ended novelty generation. We can do so by bootstrapping the system with some more sophisticated machines, some inspired directly by the biological processes of figures 4a and 5a, and some higher level ones implementing ‘non-atomic’ functionality. There is a tension between performance (composing the actions of low level machines versus the single action of a ready-made higher level machine) and flexibility (being able to compose low level machines in novel ways, and having their modifications being more likely to produce viable variant machines). The aim is to engineer a sufficiently powerful and flexible bootstrap that the system can smoothly self-modify into an open ended novelty generator.

Candidate bootstrap machines (which would need to be designed both for the implementation language, and for any application) include those to perform the following functions:

- **expression:** a machine that takes a template, and expresses (instantiates) some machine encoded there. This does not need to be restricted to simple ‘gene expression’: some machines might use information in the template in different way, for example, analogous to the use of ‘gene libraries’ in assembling antibodies. The expression machine might be ‘sloppy’, expressing a range of similar machines, with this sloppiness subject to modification.
- **modification:** a machine that takes a template, and modifies its content in some language dependent way (possibilities include low level machines analogous to transposons

[10], retroviruses [2, 23], and F-plasmids [19], and higher level machines analogous to the processes of gene error correction and crossover, for example).

- **regulation:** a machine that regulates the action of expression machines (this is not explicitly included in the UML models above, but gene regulation is a known critical aspect of biological control, and the regulation is performed by machine-class molecules).
- **replication:** a machine that replicates templates. There will be a constant turnover of templates in RNA-world analogues, and a slower turnover in the more template-stable DNA-world analogues. The replication machine should be ‘sloppy’, providing a source of variation, with this sloppiness subject to modification.
- **translation/transduction:** machines that translate between different information-bearing formats (both internal, and input/output)
- **application:** machines that perform application-specific tasks (the analogue of protein machine behaviours that are not related to modification and expression)

As well as these directly biologically inspired machines, other ‘higher-level’ bootstrap machines might be developed, to help kick-start specific kinds of novelty generation. These are inspired by even later developments in biological evolution. Such machines might include:

- **sensors:** machines that can sense the internal state of the system (for example, via quorum sensing), which information may be used by transducers, regulators, etc
- **generators:** machines that write new templates based on observed behaviours in the system (for example, ‘reverse engineering’ the composed behaviour of several low level machines into a single high-level machine, or breaking down a high level machine into component behaviours)

Other application-specific bootstrap machines can be designed as required. Design of such machines needs to respect the architecture of the system, in particular, the ‘soft’ nature of the mechanisms [4], and the continual turnover of the machines (a good solution, once found, must then be maintained).

Some of these bootstrap machines (particularly higher-level ones) will be easier to implement in high level languages than in assembly-level AChems. However, they are constrained by the particular physics of the system. For example, if the system’s physics does not support global observation, then a global observer machine will not be directly implementable in the system (however, a property akin to global observation could potentially *emerge*). Machines in high level languages can nevertheless be bootstrapped to have potentially sophisticated memories and be-

haviours. There is, however, a tension between the sophistication of the machine that allows it to perform complex functions, and the simplicity of the machine that allows it to be modified in useful ways. Any higher level bootstrap machines should be implemented as compositions of simpler machines wherever possible, allowing modification both of the machines themselves and the ways they are composed. That is, the *representation* of these machines should also be modifiable.

## Biological messiness

Bio-inspired systems are abstractions of the myriad emergent phenomena seen in biology. Their goal is to develop toolsets that *efficiently* distil the unique properties of robustness and adaptability seen in biological systems. Care has to be taken not to throw the baby out with the bathwater, however. We propose that biology generates emergent phenomena by coupling together two phenomena. The first of these is massive *redundancy and degeneracy*, observable in many biological networks: entities are rarely the ‘sole providers’ of all their functionality. This generates massive ‘baseline diversity’. The second is natural selection, which builds hierarchical emergent behaviours by reinforcing beneficial interactions. Crucially *diversity is maintained*, both within and between units of selection, allowing further interactions to be developed and built upon.

This messiness, redundancy and degeneracy that pervades biology has ‘function’, in that it provides a sort of embodied memory. It endows the system with robustness, and alternative pathways should the environment change. It is important not to simplify this away when building abstract models of the processes. In terms of the models introduced above, components should be allowed multiple interfaces, with different components realising different subsets of the complete set of interfaces.

Multiplicity and concentration of machines are an important part of this messiness. Many molecules need to exist in a concentration in order to collectively fulfil their role (DNA being the exception). Given the vast multiplicity of some molecules, ‘erroneous’ molecules that have partial functionality cannot be easily removed, if they do not result in the death of the organism before reproduction. Checking the viability of a molecular unit is an extremely expensive process in biology and is not normally attempted (DNA again being the exception). The continual decay and replenishment is the preferred mechanism. For example, the cell membrane is continually created and consumed [6], and there is a dynamic turnover of flagella motors [7].

This further suggests that there should be multiple copies of templates and machines in the computational system.

## Comparison with existing systems

We are not aware of any high level reflective language systems that fit our DNA-world framework.

A good example of such a computational system that fits our RNA-world framework is an assembly language where the executing code is able to modify the instructions ('embodied source code'). For example, consider an Artificial Chemistry such as Tierra [26], Avida [1], or stringmol [14, 15, 16], which take approaches that are direct analogues of RNA-world. Their chemicals affect and modify each other, by the computational execution of the AChem. However, none fits all the requirements of our framework.

Tierra, directly inspired by RNA-world, fits quite closely with part of our architecture, but has two major differences.

Tierra has an explicit VM to execute its assembly language, designed to be "especially hospitable to synthetic life": non-brittle and evolvable. The spatial model is provided by location in computer memory (although instructions can point to anywhere in space). The entities are analogues of "creatures of the RNA world", although the individual machine instructions are considered to be more analogous to the more chemically active amino acids than to RNA's nucleotide bases. Tierra uses CPU time-slices as an analogue of energy, with the size of the time slice being a tunable function of the entity's size: small size can be rewarded, discouraging 'bloat', or large size can be rewarded, encouraging complexity. It has a decay mechanism in the VM: killing entities when the memory space is close to full. The code can generate errors, which are used to increase the probability of the offending entity being killed. Sloppiness is hardcoded in the VM as bit-flip mutation rates (a background rate, and a higher rate on copy) [9], and through flawed instruction execution. The system is initialised with a single hand-crafted self-replicating entity.

Tierra does not fit our architecture in two important ways.

Firstly, and most importantly, although entities can read and execute the code of other entities, they can modify only themselves (each entity's memory space is write protected). This disallows the emergence of a population of mutually self-modifying entities, other than by copying foreign code into the host entity (a 'pull', rather than a 'push', mechanism). It is a model of single active machines, not of mutually interacting machines mutually defining their properties. This design decision, along with making a less 'brittle' programming language, was made with the aim of overcoming problems in earlier 'Core Wars' implementations (eg, [25]), where mutations mostly just destroyed the system. We believe that the biological inspiration strongly supports mutual modification, however, and that the routes to overcoming the Core Wars issues are a more sophisticated energy model, and a 'softer' language, particularly in respect to binding properties [4].

Secondly, the Tierra energy model is limited. There is no analogue of an energy store (battery, fat reserves) that would enable entities to 'time-shift' their use of the resource, or hand on a surplus to their progeny; Tierra is a 'use it or lose it' model. (Ray [26] mentions a possible extension allowing

capture of CPU slices.) Nevertheless, Tierra evolves an interesting diversity of entities, particularly a range of parasite types.

Avida, although directly inspired by Tierra in the sense that it is an assembly-language based AChem using CPU time slices as a selection pressure, has a very different architecture and motivation from our approach. Entities, in fixed locations in 2D space, interact only with their neighbours, and then only through replication, which copies the replicated entity over its oldest neighbour. Bonus time slices, which can accumulate, are used as an explicit reward mechanism to evolve entities to perform certain tasks.

Stringmol is an assembly language AChem that fits our architecture quite closely, but not perfectly. It is a 'soft' replicator system that has generated novel emergent macro-mutations and hypercycles (two co-dependent species that replicate each other, but are not self-maintaining) [4, 14]. Its execution model involves two strings, and active machine and a passive template; however execution can change either string. The system is initialised with multiple copies of a hand-crafted replication machine, that can replicate any template string it binds to. We have not investigated its behaviour with other kinds of bootstrap machines.

Stringmol has an explicit energy model, in that a certain number of units are added to the container at each timestep, and molecules need to use an amount to execute each instruction. Hence there is a pressure to be small, to enable faster replication cycles. However, the energy is a global resource (energy is not stored in individual entities, but in the system and accessible to all). This removes any incentive for an individual entity to be frugal (beyond replication speed); stringmol exhibits the 'free rider' problem.

## Summary and Conclusions

Biology uses a variety of processes to generate novelty and robustness. Fundamental is the capture of genomic information in an *embodied* genome (DNA or RNA) that is the same kind of structure (molecule) as the active machinery (RNA or proteins). This embodiment allows the active structures to interact with, control, and *modify* the information that defines them. Once novelty has been generated, it can be specialised into different components (DNA as information template, protein as active machine), allowing more effective behaviours to evolve, as the competing requirements of different behaviours are isolated in different components. Specialisation of template and active machinery is aided by different representations (at some level), which require a translation step from information encoded in the template to its expression in the machinery. Specialisation should not go too far: degeneracy and redundancy are also crucial components of biological robustness and adaptability.

Taking these concepts, and abstracting them, we can develop a set of requirements for analogous AChem and ALife implementations: (1) run-time metaprogramming, where

the executing system changes the program that defines its execution, including novelty generation as addition of interfaces; (2) a physics engine VM; (3) specialisation in terms of removal of interfaces (either explicitly, or implicitly by separation of implementation structure); (4) an expression step that decodes information on the template into a different representation on the machine (allowing different kinds of behaviour); (5) redundancy and degeneracy in terms of allowing multiple interfaces per component, and multiple copies of components; (6) sufficiently sophisticated bootstrap machines to short-circuit the origin of life process.

We claim that a suitably ‘rich’ computational environment based on an embodied, modifiable genome that allows novelty generation (adding interfaces) and specialisation (removing interfaces) is a necessary component in maintaining diversity and producing novelty.

## Abstract

We present a fully detailed design of the very first *synchronous single-input* delay flip-flop (or BioD) implemented as a gene regulatory network in *Escherichia coli* (*E. coli*). The device has one data input (trans-acting RNA), one clock input (far-red light) and an output that reports the state of the device using green fluorescent protein (GFP). The proposed (simulated but not synthesized) device builds on the toggle switch of (Gardner et al., 2000) to provide a more sophisticated device that can be synchronized with other devices in/out of the same cell, and which requires only one input. We provide the first results of a deterministic simulation of a mathematical model of the new device, one which provides evidence that the device is likely to work as required when actually synthesized.

## Introduction

The complex processes that take place in a cell are governed by gene expression which is regulated at several levels during the pathway leading from DNA to protein. Apart from the regulation at the DNA level, gene expression may be regulated during transcription, post-transcription, translation, and during post-translational modification of proteins. Notably, much of the control of gene expression is done either by the regulatory proteins or by mRNAs which are essentially the products of other genes. Hence, the interactions between DNA, RNA, proteins, and other molecules, form a gene regulatory network (GRN). While examining these components individually has provided invaluable information, it is essential (a) to thoroughly investigate these components in variable environments and/or performing variable functions, and (b) to integrate this knowledge to generate valuable genetic devices. Here comes the role of synthetic biology that aims at systematically designing, building, combining and testing new biological functions and systems that do not occur in nature. Indeed individual parts such as promoters and transcription factors can be assembled to synthesize GRNs that perform desired functionalities, such as computing machines.

The synthesis of computing machines via the manipulation of DNA (within or without living organisms) started in 1994 when Adleman executed an experimental procedure that used DNA, in vitro, to solve an instance of the directed Hamiltonian path problem (Adleman, 1994). In contrast, in vivo cell-based or cellular computing started in 1998 with the

modification of the genome of prokaryotic cells (typically *E. coli*) to realize one- and two-input combinatorial Boolean logic gates (e.g. NOT, AND and IMPLIES) (Knight, Jr. and Sussman, 1998; Weiss et al., 1998); and a similar feat recently was achieved with eukaryotic cells by Kramer (Kramer et al., 2004). Along another dimension, time-dependant or sequential Boolean logic devices have also been implemented in living cells, starting most notably with a 2-input toggle switch by Gardner (Gardner et al., 2000), and a synthetic oscillator by Elowitz (Elowitz and Leibler, 2000). In fact, in one decade this field has grown to generate many elementary devices (Drubin et al., 2007; Boyle and Silver, 2009; Tigges et al., 2009; Haynes and Silver, 2009), including band-pass filters (Stricker et al., 2008) and counters (Friedland et al., 2009). More complicated devices like engineered multicellular pattern generators (Basu et al., 2005), single cell biosensors (Levskaya et al., 2005; Tecon et al., 2006), tumor-targeting bacteria (Anderson et al., 2006), and cell-based computers (Cox, III et al., 2007; Balagadde et al., 2008) have also been built or proposed.

Despite the numerous works on genetic switches, all proposed designs work *asynchronously*. This means that the switch's operation cannot be synchronized with the operation of other parts, using a single global clock. Henceforth, we call a *synchronous single-input delay* switch a *BioD*; a novel GRN that changes states in response to a clock signal by having its output expression follow its input.

## Circuit Design and Modeling

BioD is a synthetic *E. coli* cell that expresses a gene regulatory network acting as a delay switch. By delay switch, we mean a logical device that has an input (*D*), a clock (*CLK*), and an output (*Q*) equal to its state (*S*); see Figure 1 (*Q* is the

**Figure 2.** Gene regulatory network for BioD. The network consists of three sections. *STATE* reflects the state of the network. *SELECTION* affects the *state* switch when the far-red light signal is ON. *INPUT* drives the *selection genes*' activation.

second output and is equal to the logical complement of  $Q$ ). The state of a delay switch is held constant unless and until its input differs from its state, on the rising edge of the clock. In that case, the next state of the delay switch will copy the value of the input (i.e.,  $Q = D$ ). Hence, a cell that acts as a delay switch is effectively a 1-bit memory device, controlled by an input and a clock. The BioD also exhibits its state by expressing (or not) a fluorescent protein.

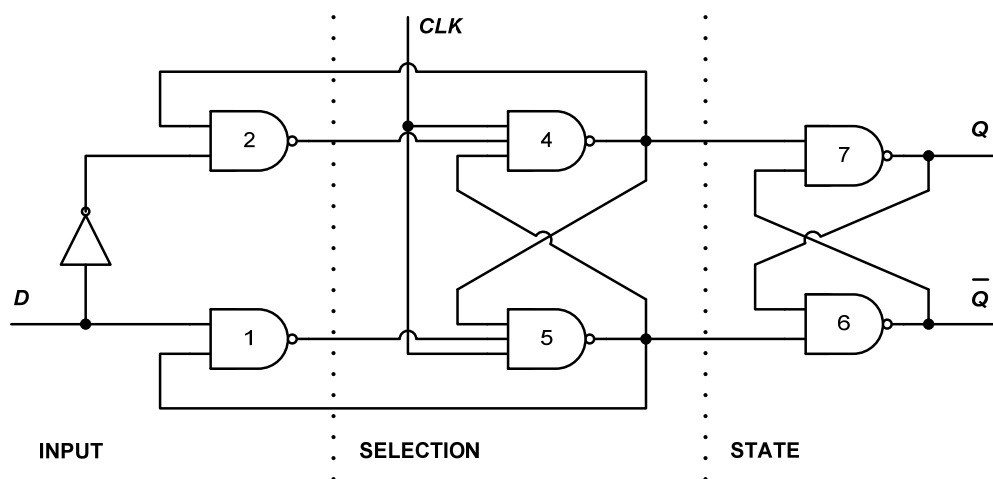

### BioD

BioD has two inputs: *trans-activating* RNA or *taRNA* as input  $D$ , and the presence or absence of far-red light as the clock ( $CLK$ ). It has two complementary outputs ( $Q$  and  $\bar{Q}$ ) defining the state of the flip-flop: the ON state is indicated by the presence of green fluorescence, while the opposite OFF state

is indicated by its absence. As with its electronic counterpart, the output follows the input on the rising edge of the clock. The gene network is comprised of three parts: *input genes*, *state genes* and *selection genes* (as shown in Figure 2).

**Input Genes.** The *input genes* convey to the *selection genes* whether an input signal is present or not. They do so by tipping the balance of the dual-repression of the *selection genes* – discussed below.

In order to sense input  $D$ , gene 1 is designed to be self-repressed, but in such a manner that can only be induced by  $D$ . To achieve this, a form of ribo-regulation is used called *cis*-regulation – which means “acting from the same molecule”. The *cis*-regulation or in our case, *cis*-repression prevents the translation of the gene 1 transcripts by causing them to bend and cover the ribosome binding site (RBS) like a

**Figure 3.** Logic diagram of *BioD* (provided here for simplicity). The above circuit behaves much like the GRN in Figure 2. It is not an exact representation of course, but helps follow the steps the circuit takes to change states. Gene numbers above are matched to gate numbers here. A low  $CLK$  signal neutralizes the selection gates 4 and 5, and sends a high signal (or identity for NAND gates) to the state gates 6 and 7; keeping them unchanged. Since the outputs of input gates 1 and 2 are complements, when the  $CLK$  signal is turned ON, only one of gates 4 or 5 becomes active and thus (i) affects one of the state gates (6 or 7) and (ii) disables its enabling input gate (gate 1 or 2). The input gates are re-enabled after the  $CLK$  goes low, leaving them free to respond to input  $D$ .

lock. The key, comes in the form of trans-activating RNA (taRNA) which, when matched with the *cis*-repressed RNA, unlocks the RBS allowing translation (Isaacs et al., 2004). The taRNA chosen for input *D* is *taR12* which unlocks the *cis*-repression we introduced in gene 1, namely *crR12*.

When the input *D* is present, the transcripts of gene 1 get translated into *cI* proteins (from the  $\lambda$  phage). *cI* in turn represses gene 2. In the absence of input *D* however, the *cis*-repressed transcripts of gene 1 do not get translated into proteins, lifting the repression of gene 2 and allowing its expression.

The presence of input *D* results in the production of the *cI* protein, while its absence results in the production of the *cII* protein (from the P22 phage).

**State Genes.** The *state genes* are very similar to Gardner's toggle switch (Gardner et al., 2000). They consist of two co-repressed genes (i.e. only one expressed at a time), and as such define the state of the BioD device. Genes 7 and 6 represent the complementary outputs *Q* and  $\bar{Q}$  respectively. A green fluorescent protein (GFP) signals the output *Q*, while its absence signals the complementary output  $\bar{Q}$ . The co-repressed nature of the toggle switch means that when either gene is active, it enters into a stable state where it represses the other, and insures its own continued expression. In our case, that stable state can only be affected by the *selection genes*.

As can be seen in Figure 2, the *selection genes* can affect the *state genes* independently of the current state of the BioD. As will be discussed below, genes 4 and 5 are mutually exclusive when active; protecting the *state genes* from conflicting signals. Furthermore, they will either reinforce the repression currently in place in the *state genes* (resulting in no state change), or they will repress the presently dominant gene until the balance is tipped, and the other takes over the state of the device. Which of the two genes 4 or 5 is activated depends on the *input genes* at the time the *CLK* signal is turned ON.

**Selection Genes.** The *selection genes* are always OFF until turned ON by far-red light (the *CLK* input). In the absence of far-red light, genes 4 and 5 are always repressed by the phosphorylated version of OmpR, i.e. OmpRP. Gene 3 is constitutively expressed and produces OmpR. OmpR is phosphorylated in the presence of the EnvZ enzyme. EnvZ is connected to Cph1, which in the presence of far-red light, induces a conformational change in EnvZ preventing the phosphorylation of OmpR. The genes that produce EnvZ and Cph1 (and a few others needed for the light response system (Levskaya et al., 2005)) are not shown in Figure 2.

The phosphorylation of OmpR is dominant in the absence of far-red light and negligible in its presence. Therefore, the far-red light signal causes a drop in OmpRP levels and a corresponding rise in OmpR levels. This drop affects genes 4 and 5 using their promoter, as *ompf* is both activated by OmpR and repressed by OmpRP. Both the functionality of *ompf* and the complementary levels of OmpR and OmpRP result in a system that is quick to start or stop transcription in both genes 4 and 5.

The *selection genes* also respond to and affect the *input genes*. As previously mentioned, BioD is an edge-triggered device, i.e. it responds to the input when the *CLK* signal turns

on, but not to a change in the input when the *CLK* signal is on. This is achieved by designing genes 4 and 5 to only be turned off by the *CLK* signal. When far-red light is introduced, and one of genes 4 or 5 turns on, that gene immediately starts repressing the genes that can potentially repress it; namely, gene 4 represses genes 2 and 5, and gene 5 represses genes 1 and 4. As a result, any change in the input *D* when the *CLK* signal is already on, does not translate to the *selection genes* until the *CLK* signal is turned off, and the repression of the *input genes* is lifted.

Given that the dynamics of such a gene network are non-trivial, we provide a single fully detailed scenario tracing through one important sequence of transitions. The scenario is that of a change of state, from OFF to ON, in response to a turned ON input (*D*), whose level must stabilize, prior to the introduction of the *CLK* signal (far-red light clocking). When the state of the BioD is OFF, gene 6 is ON, expressing two products. Since one of them (TetR) is repressing gene 7, gene 7 is considered OFF. In the absence of red light, the constitutively expressed (and subsequently phosphorylated) repressor (OmpRP) blocks any production from the *selection genes* (4 and 5). Hence, the status quo of the *state genes* is maintained. Lastly gene 1 is ON, induced by the input (*D*), while gene 2 is OFF, repressed by the product of gene 1, namely *cI*. After clocking, the concentration of OmpRP (which was repressing genes 4 and 5) starts falling. The only other repressor of gene 4 (i.e. *cII* from gene 2) is already OFF. So gene 4 can start producing, and as such, it starts repressing gene 5, which is still repressed by *cI* from gene 1. At this stage, gene 1 is ON, gene 2 is OFF, gene 4 is ON, gene 5 is OFF, while gene 6 is still ON and gene 7 is still OFF. Turning our attention to gene 4, note that one of the repressors it produces is identical to the one generated by gene 7, namely *LacI*. Its production starts switching off gene 6, resulting in a gradual increase in the expression of gene 7. Once gene 7 is fully expressed, it represses gene 6 (via its own *LacI* protein), ensuring the continuation of gene 7's new ON state. Hence, we have achieved a network change of state (indicated by GFP) from OFF to ON (following the value of the input (*D*)). For as long as the *CLK* signal is ON, the new state is maintained. If a significant change in the input level occurs while the clock is ON, the repressions of genes 2 and 5 would not disappear, since gene 4 is ON and produces *cI*. Indeed, as long as gene 4 is ON, it has the ability to keep itself from being repressed by other genes, that is, by repressing them. It is only when the *CLK* signal is removed and both genes 4 and 5 are OFF that the system is free to respond to the input (*D*) again.

### Model

The network in Figure 2 is simulated deterministically. The fast reactions (not shown) involve the binding of proteins to one another and to the DNA. The slow reactions (shown below) involve transcription of mRNA and translation of proteins. The important reactions are presented here as a single combined process.

We define the following terms and chemical species:  $D^{(n)}$ , the DNA protein-binding site in the promoter of gene *n*;  $D_X^{(n)}$ , the  $D^{(n)}$  bound by repressor/activator *X*; *P*, RNA polymerase;  $k_n$ , rate of production of gene *n* (promoter strength);  $k_n^{[1]}$ ,

effective production rate of gene  $n$  after repression/activation;  $\eta_X$ , number of proteins molecules per transcript of gene  $X$ .

where  $CI^*$  depicts the  $cI$  protein that is produced by the *cis*-repressed transcripts of gene 1 – therefore is dependent on input  $D$ .

We simulate the device using a system of rate equations with the concentrations as the dynamical variables. A timing diagram is displayed in Figure 4.

## Results & Discussion

We presented the design of a gene regulatory network (GRN) that, if synthesized and integrated into the genome of an appropriate strain of *E. coli*, will give us a single-cell synchronous single-input toggle switch (we call the *BioD*). The *BioD* accepts as input trans-acting RNA, which allows it be linked to other GRNs; it is clocked using far-red light, which allows external synchronization of its operation; it indicates its state by expressing green fluorescent protein (GFP), which allows easy external monitoring of the state.

The whole design is modular in that it allows alteration of the input sensing and output expression parts without affecting the toggling functionality of the device.

In the sequel, we present the results of simulating the device using a system of rate equations. The results confirm our expectation that the device will toggle when and only when required – though its speed can still be improved.

## Simulation

The core functionality of our *BioD* device is illustrated in Figure 4. The highlighted areas indicate the presence of an input. The reddish hue reflects the presence of the clock input ( $CLK$ ), while the grey diagonal pattern reflects the presence of the data input ( $D$ ). The examples provided have two different data cycles intersecting (or not) with four different clock cycles. This setting allows us to show that the device can indeed go from one state to the other with nothing more than the introduction of the inputs it was designed to respond to; in other words, the device does not get stuck in any one state.

Ideally, with four separate  $CLK$  inputs, the state of the device should follow the  $D$  input four times. In this case, the state should turn ON, then OFF, and then OFF again and finally ON. Figure 4a displays those exact state changes in a deterministic run whose initial condition is an OFF state. The normalized GFP expression output follows the input only at the rising edge of the clock. However while the clock is ON or is OFF, any changes in the input do not propagate to the output. This plot is used to demonstrate the overall input/output relationship. Figure 4b shows the changes in the protein levels – here the levels of  $LexA$  and  $GFP$  were not displayed because they do not affect the behavior of the device.

In the ON level, the expression of a substance is defined mainly by its rates of synthesis and degradation. As expected, some proteins have multiple stable levels of expression. Since  $cI$ ,  $cII$ ,  $LacI$  and  $TetR$  are not only produced in the *selection genes*, but can also be found in either the *input* or *state genes*, the expression of those proteins is significantly increased with the presence of the  $CLK$  signal.  $TetR$  has four levels of expression: (i) OFF, (ii) gene 6 is ON, (iii) gene 5 is ON, and (iv) genes 5 and 6 are ON.  $LacI$  has similar levels of expression using genes 4 and 7. In the case of  $cI$  however, since gene 4 can only turn on if gene 1 is active, it only has three levels of expression (and similarly for  $cII$ ).

Tracing the various signals in Figure 4b shows that, the simulation starts with two active proteins,  $TetR$  (the state of the device is OFF) and  $cII$  (unrepressed since input  $D$  is OFF). Here is a step-by-step explanation of the changes seen in the timing diagram.

First, input  $D$  is introduced, causing the repression of gene 2 (or  $cII$ ) to start. Since gene 1's transcripts are now translated and gene 2 is OFF, gene 4 becomes on an edge-trigger to be turned ON, while gene 5 is doubly repressed by  $OmpRP$  and now by  $cI$ . The  $CLK$  signal is introduced, stopping the phosphorylation of  $OmpR$  and activating gene 4. This raises the levels of  $cI$  and  $LacI$ . The latter represses gene 6 and starts turning the state of the device ON. As  $TetR$  fades away, the GFP levels start climbing. Then the  $CLK$  signal is turned OFF followed by the input  $D$ . These two actions turn OFF gene 4 and disable gene 1 respectively. With both inputs OFF, the  $cI$  repressors produced by genes 1 and 4

**Figure 4.** Deterministic simulation of *BioD*. The two timing diagrams are displaying different signals of the same run. The highlighted areas indicate the presence of an input. The red hue indicates the *CLK* signal (FR light). The grey diagonal pattern indicates the presence of the input *D*. **a.** Normalized GFP expression **b.** Protein levels

degrade without replacement allowing *cII* to return to its previous level. *LacI* which is now produced by gene 7 reaches its un-repressed (ON) state equilibrium.

The second state change occurs when the *CLK* signal is turned on again. Since *cII* is expressed at that time (no input *D*), gene 5 turns ON, causing the repression of gene 1 (through *Gal4*) and the repression of gene 7 (through *TetR*), and raising the level of *cII* (as it is produced by both genes 2 and 5). When the *CLK* is removed, gene 5 is turned OFF, but *cII* and *TetR* remain high, while *Gal4* is repressed. Note that the *TetR* levels are now produced by gene 6 (which took over the state of the toggle switch from gene 7), and no longer by gene 5.

The third *CLK* signal starts now. Gene 5 is again turned ON; the levels of *cII*, *Gal4* and *TetR* climb. In the middle of the *CLK* pulse, the input *D* is introduced. This causes no change in the network. Since input *D* only affects gene 1, its effects were muzzled because the clock had already turned on gene 5 which repressed gene 1. It is only after the clock is turned OFF that the gene 1 repression is lifted. At this point, even though the *CLK* signal is removed, the input *D* is still present, and since gene 1 is no longer repressed by gene 5 (or *Gal4*), *cI* is translated and represses gene 2. The state of the device however does not change since the *state genes* are not directly affected by the *input genes*.

The fourth *CLK* signal turns the state of the device back ON. In the presence of input *D*, the *CLK* turns gene 4 ON causing a similar sequence of events witnessed following the first *CLK* signal.

### A Note Regarding Frequency

The frequency of operation of the *BioD*, that is to say the frequency at which the device can change its state in response to the input is closely related to the genes used to build the network. Indeed, while the design of the *BioD* allows for the use of other genes than the ones presented in this paper,

different genes do have different properties modeled by different synthesis rates, degradation rates, diffusion rates, and promoter/repressor dissociation constants, to name a few. All of these parameters indirectly control the time it takes for the system to respond to an input change, and the time it takes to finish a state change and reach a steady state.

In our case, and when going from an OFF to ON to OFF state, the *CLK* signal had to be sustained for at least 22 minutes to get a sustained state change, while it had to be removed for at least 64 minutes for the network to regain its steady state. That gave the smallest period (or max. frequency) of approximately 86 minutes (5160 seconds).

### A Note Regarding Speed

Speed is a main area of improvement. Indeed, the slowest reactions in a cell are the ones involving repressors and ultimately their transcription and translation. The time it takes to fulfill these operations depends on the promoter strength, the coding sequence that is being transcribed/translated, and the presence of RNA polymerases and/or ribosomes nearby. The impact of repressors is further delayed until the mature protein manages to hit the proper operator site, at the right angle and speed. Using post transcriptional regulation like *taRNA* or RNA interference (RNAi) where possible to effect the state change in *BioD* will make the system significantly faster. The first such place would be where the *selection genes* interact with the *state genes*. Instead of producing repressors for genes 6 or 7, the use of RNAi to prevent one of them from translating repressor proteins would make the entire system significantly faster. Since we already make use of *taR12* to sense the input, we would therefore need another two independent riboregulators that do not interfere with *taR12* or with each other.

## Conclusion & Extension

In this paper, we sought a proof of concept for the first synchronous single-input delay flip-flop implemented as a gene regulatory network in *E. coli*. The simulation we present provides evidence that the device can toggle from the ON state to the OFF state and back, according to the intended functionality. The inherent symmetry of the design reduces the number of genes needed for the device, but introduces some complexity (which is palpable when tracing the various changes the device goes through when toggling).

The BioD is effectively a 1-bit memory element that can operate synchronously (on a clock) with any number of other elements. As such, it can be used to hold the state of a finite state machine, but it could also be used to build a memory bank, an event sequence detector/effector, a decision-making system, and numerous other memory-requiring devices.

## Abstract

Humans are able to perform an unlimited repertoire of reaching movements with high accuracy. The skillfulness with which we carry out a given reaching task suggests that there are fundamental control policies that allow us to move our body. In the current paper we examine how an adaptive reach policy can be established, using biologically inspired techniques. The developed model, after an initial imitation phase, can replicate any given trajectory with very good performance.

## Introduction

Reaching is a demanding task, due to the difficulty that lies in the coordination and control of the high-dimensional kinematics of the arm. Despite this fact, primates are able to perform it quite effortlessly. To interface between the symbolic level, that everyday tasks are described, and the low level of motor coordination, the brain uses several intermediate stages of processing (Atkeson, 1989). The richness of human motor abilities suggests that these stages allow the adaptive control of our body, by generalizing motor knowledge to other tasks and directions of movement. Much of this ability to reach is acquired during the early developmental stages of imitation (Piaget, 1962), where infants learn to regulate and control their complex musculoskeletal system.

Reaching motions have widely been studied in order to understand the brain structures that facilitate motor control. Research has revealed that the cerebral cortex uses several different cognitive processes to accomplish this goal, including kinematic (Atkeson, 1989) and dynamic (Soechting and Flanders, 1992) representations of movement, combined with forward and inverse models (Wolpert, 1997). To reduce the complexity of regulating all these processes, the brain makes use of modular structures (Ballard, 1986). Modularity is realized in various levels of the cognitive processing hierarchy and serves to hide the low level spinal system from the higher control centers of the cortex, allowing proper reuse of the motor knowledge.

At the spinal level, converging evidence suggests that modularity is implemented by a pre-coded set of control modules known as primitives (Degallier and Ijspeert, 2010). This concept has received considerable attention in the field of engineering. From a mathematical perspective the method of primitives, or basis functions, is an attractive way to solve the complex nonlinear dynamic equations that are required for motor control. For this reason several models have been proposed, including the VITE model that describes a way to regulate sets of agonist and antagonist muscles to move the limb to a desired state or the FLETE model that consists of a

fixed parameterized system of differential equations that produce basis motor commands (see Degallier and Ijspeert, 2010 for a review). More recent studies in vertebrates suggest a force dependent encoding of motor primitives. For example experiments in paralyzed frogs revealed that limb postures are stored as convergent force fields (Bizzi et al, 1991). In (Giszter et al., 1993) the authors describe how such elementary basis fields can be used to replicate the motor control patterns of a given trajectory.

To be able to reach adaptively, the agent must learn to manipulate its primitives using control policies that generalize across different behaviors. In the cerebral cortex one of the dominant themes used for learning is by receiving rewards from the environment. This paradigm, known as reinforcement learning in engineering, does not require an exact learning signal of the error but rather a scalar, temporally delayed, reward function (Barto, 1995). It is more consistent with the type of feedback provided to humans during learning, where exact information on the error is usually not available. An agent that learns based on reinforcement learning tries to find a policy that will maximize the probability of receiving immediate or future rewards.

In the current paper we investigate how a simulated agent can learn an adaptive reaching policy using methods inspired from biological systems. To accomplish the low level motor control we employ the notion of force fields to design higher order primitives, i.e. motor programs that facilitate the synergetic control of multiple joints. Learning is implemented by modeling the circuitry of the dopaminergic neurons that are responsible for the perception of rewards in the cerebral cortex, and using it to form an adaptive control policy for reaching.

The proposed model consists of several interconnected regions. The roles of these regions are derived based on evidence from imaging and lesion studies that describe their cognitive functions. To implement the modularity at the cortical level we break down the whole system into pathways, i.e. sets of inter-dependent regions that carry out a specific process (Hourdak and Trahanias, 2009). The computational areas in each pathway are modeled using liquid state machines (LSMs, Maass et al, 2002). LSMs consist an alternative to the traditional finite-state machine methods for brain modeling. Their difference lies in that they do not require any convergence to attractor states. Moreover, they are consistent with the homogeneity inherent in the cortical regions where different processing functions are carried out by similar structures (Mountcastle, 1978). To accomplish this dynamic form of processing, LSMs perturb neuronal populations using

continuous or discrete input signals. A large variety of functions can be learned from this perturbation using readout neurons, i.e. neurons implemented with traditionally supervised learning methods. Recently it has been shown that LSMs can carry out any computation with fading memory, provided that the properties of separation and approximation are fulfilled (Mass et al 2002; Hourdakis and Trahanias, 2011).

In the following sections we describe the development and evaluation of a reaching model that is inspired by the aforementioned cortical processes. We begin by examining the biological evidence that underpins the model, and continue to describe the implementation of the model and its evaluation.

## Computational Model

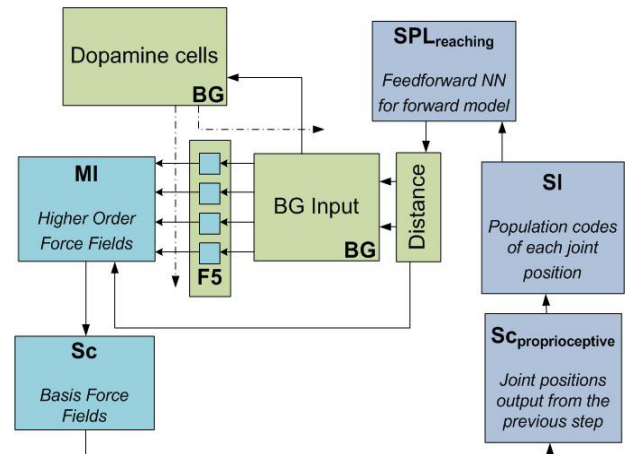

### Cortical model

The central nervous system performs reaching by transforming sequential target locations into muscle commands that move the hand to a desired state (Soechting and Flanders, 1992). To relate the intrinsic proprioceptive state of the agent to extrinsic behavioral goals, such as the points in a trajectory, a forward transformation must be learned (Wolpert, 1997). Anatomical evidence from imaging studies suggest that the cerebral cortex learns such transformations using supervised learning (Doya, 1999). The forward model is implemented in the connections of the primary somatosensory cortex, where the proprioceptive state of the arm is encoded (Sergio and Kalaska, 2003), to the parietal lobe, which is responsible for state estimation. After the behavioral goals have been established, using the forward model and perception, reaching can be accomplished by the adaptive control of primitives. Data from animal lesions and human studies (Sakai et al, 1998) suggest that the basal ganglia are one of the main regions involved in learning sequential movements. This is accomplished by processing the rewards of the environment, which in the brain are evident from the secretion of dopamine, in order to gate motor programs (Thach et al, 2000). Learning of new motor policies is implemented in the projections of the basal ganglia with regions of the prefrontal cortex, where segments of motor acts are encoded (Jeannerod et al., 1995), and primary motor cortex, where the neurons' activity is strongly correlated to the level of activation of individual muscles (Todorov, 2000). Finally, lower level control is mediated by the connections of the primary motor cortex to the spinal cord (Dum and Strick, 1991).

To model the interaction between the sensori and motor systems in the cerebral cortex we use the notion of pathways (Hourdakis and Trahanias, 2009). Each pathway implements a distinct cognitive function and is defined by two factors: (i) the regions that participate in its processing and (ii) the directionality of the information as it progresses the levels of the cognitive hierarchy. This type of abstraction helps to identify and describe at a computational level how cognitive functions are carried out neurally. As a result development of

the model becomes a two stage process; first individual cognitive functions are designed, and then integrated together in order to achieve the required behavioral tasks. The modularity induced by pathways allows us to overcome traditional problems with large scale distributed architectures, such as cross talk. This type of modular approach provides important benefits in computational modeling since it allows identifying how the complex processes that exist in biological systems can be modeled with computational principles.

To design a reaching model, we identify three different pathways: (i) motor control, (ii) reward assignment and (iii) forward model. These are displayed in the following figure, where each pathway is marked with a different color.

**Fig. 1.** The complete layout of our model with the three pathways, motor (blue), reward assignment (green) and forward model (purple).

Motor control (marked in blue) is responsible for the encoding of the primitive model. It includes regions **Sc**, where a set of basis primitives are hardwired, **MI**, where the basis modules are combined into higher order control modules and **F5**, where the higher order control modules are synthesized based on an adaptive reaching control policy. The latter is learned implicitly through the reward assignment pathway (marked in green). Finally the forward transformation of the body-centered state of the agent is accomplished in the forward (marked in blue) pathway. In the proposed model there is also an additional visual perception pathway that handles the perception of the trajectory. However, due to space constraints, in the current paper we assume that the trajectory is given to the agent as a series of consecutive points. In the following sections we describe the mathematical framework that underpins our model, as well as the implementation of each pathway.

### Arm control

To model the effect that the torques have on the joints of the robot we use established laws from control theory (Paul, 1981). The second order kinematics of the robot hand are modeled using the following equation:

$$D(q, \dot{q}, \ddot{q}) = H(q)\ddot{q} + C(q, \dot{q})\dot{q} \quad (1)$$

where  $D$  is the controller that produces the torques that must be applied on the joints of the robot given its state  $q$ , and its first and second order derivatives,  $\dot{q}$  and  $\ddot{q}$  respectively.  $H$  is the joint-space inertia matrix and  $C$  describes the Coriolis and centripetal effects from the joint movement. Eq. 1 can be extended with additional terms such as the viscosity of the joints or the gravity loading of the plant. In the current paper, we applied the model on a simulated frictionless two-link plant, and therefore we didn't include these parameters.

The aim of the computational model is to derive the appropriate local control laws that will allow the plant to reach towards any location. In practice we look for a control policy that will map the state vector of the robot to a control vector from the computational model in a way that minimizes the error of reaching. Degallier and Ijspeert (Degallier and Ijspeert, 2010), suggested that such a control policy  $\pi$  can be defined as:

$$v = \pi(q, t, a) \quad (2)$$

where  $v$  are the joint torques that will be applied to the robot,  $q$  is the state space vector,  $t$  stands for time and  $a$  is the parameterization of the computational model.

The output of our model is the signal produced by the spinal cord circuit. In a biological agent the torques produced would be applied to the hand and result in movement. However since we use a simulated agent we find the second order kinematics of the hand by integrating eq. 1 and solving against the acceleration:

$$\ddot{q} = H(q)^{-1} \{ \tau_p - C(q, \dot{q}) \} \quad (3)$$

The next configuration state of the robot is calculated using the acceleration  $\ddot{q}$  from the equation above, where  $H$ ,  $C$ ,  $q$  and  $\dot{q}$  are as in eq. 1. The goal of the computational model is to produce the appropriate  $\tau_p$  vector of joint torques that will enable the agent to perform reaching.

To evaluate the proposed model we use a simulated two-link planar arm. Control is accomplished by applying torques to the elbow and shoulder joints respectively. Therefore in the presented simulations the  $\tau_p$  vector is two dimensional.

### Forward model pathway

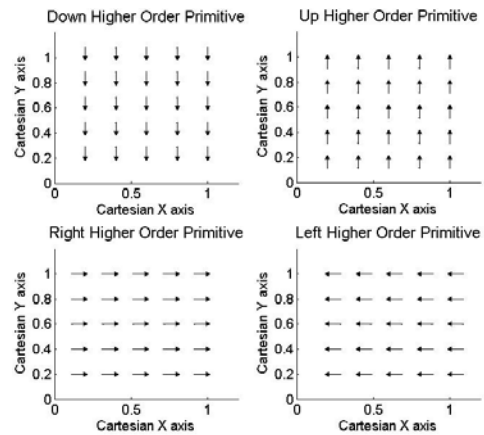

One of the main transformations that takes place during reaching is the cognitive implementation of a forward model (Wolpert, 1997). In the current paper, the forward model is implemented in the regions of the somatosensory and parietal lobe, and allows the agent to approximate the end point position of its hand using the proprioceptive input from the spinal cord.

To accomplish this we have designed the SI network to encode the proprioceptive state of the agent using population codes. This is inspired from the local receptive fields that exist in this region and the somatotopic organization of the SI (Kaas et al., 1979). Population codes assume a fixed tuning profile of the neuron, and therefore can provide a consistent representation of the encoded variable. To learn the forward transformation we train a feedforward neural network in the SPL region that learns to transform the state of the plant to a Cartesian x, y coordinate.

### Motor pathway

Due to the high nonlinearity and dimensionality that is inherent in controlling the arm, devising an appropriate policy for learning to reach can be quite demanding. In the current paper this policy is established upon a few higher order primitives, i.e. self-organized spinal circuits that coordinate elementary motor behaviors. It turns out that, in the adopted planar arm, in order to perform any reaching behavior, only four higher order primitives are required namely up, down, left and right (Fig. 2). In humans such modules are formed during the first stages of the vertebrate motor development.

In order to make the agent generalize motor knowledge to different domains, the primitive model must be consistent with two properties: (i) superposition, i.e. the ability to combine different basis modules together and (ii) invariance, so that it can be scaled appropriately. Primitives based on force fields satisfy these properties (Giszter et al, 1993). As a result by weighting and summing the four higher order primitives shown in Fig. 2 we can produce any motor pattern required.

**Fig. 2.** The higher order primitive model proposed. The four plots show the force map of the primitive, i.e. the forces that are applied to the end position of the limb when the corresponding primitive is active. In the current model we use four different modules, namely up, down, left and right.

The higher order primitives are composed from a set of basis torque fields, implemented in the Sc module. By deriving the force fields using basis torque fields, the primitive model creates a direct mapping between the state space of the robot (i.e. joint values and torques) and the Cartesian space that the trajectory must be planned in (i.e. forces and Cartesian positions), resembling the way motions are processed by humans. We first define each torque field in the workspace of the robot, and then transform it to its corresponding force field. Each torque field is described by a Gaussian multivariate potential function:

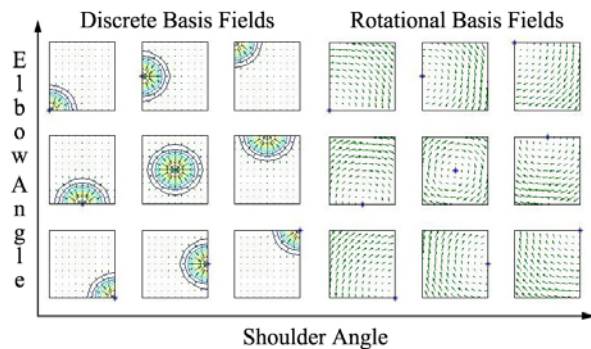

$$G(q, q_0^i) = -e^{\left( \frac{(q - q_0^i)^T K^i (q - q_0^i)}{2} \right)} \quad (4)$$

where  $q_0^i$  is the equilibrium configuration of each torque field,  $q$  is the robot's angle and  $K^i$  a stiffness matrix. The torque

applied by the field is derived using the gradient of the potential function:

$$\tau^i(q) = \nabla G(q, q_0^i) = K^i(q - q_0^i)G(q, q_0^i) \quad (5)$$

Previous research has indicated that in order to achieve stability, two types of primitives must be defined: discrete and rotational (Degallier and Ijspeert, 2010). The rotational primitives are harmonic oscillators associated with a joint. The discrete ones apply a force on the hand based on a shaped valley with different equilibrium points. To ensure good convergence properties we have used 9 discrete and 9 rotational basis torque fields, spread throughout different locations of the robot's workspace (Fig. 3). These are generated from eq. 5 using different stiffness matrices. To generate the discrete torque fields (left block in Fig. 3) we use a semi-definite skew symmetric matrix  $K_{disc}$ , while to generate the rotational fields we use a rotation matrix,  $K_{rot}$ .

**Fig. 3.** Nine basis discrete (left block) and rotational fields (right block) scattered along the  $-\pi.. \pi$  configuration space of the robot. On each subplot the x axis represents the elbow angle of the robot while the y axis represents the shoulder angle. The two stiffness matrices used to generate the fields are  $K_{disc} = \begin{bmatrix} -0.672 & 0 \\ 0 & -0.908 \end{bmatrix}$  and  $K_{rot} = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}$ .

Each plot in Fig. 3 shows the gradient of each torque field. The axes correspond to the  $q_1, q_2$  joint values of the robot's hand. Since we want the model of higher order primitives to be based on the forces that act on the end point of the limb, we need to derive the appropriate torque to force transformation. To accomplish this we convert a torque field to its corresponding force field using the following equation:

$$\varphi = J^T * \tau \quad (6)$$

In eq. 6,  $\tau$  is the torque produced by a torque field while  $\varphi$  is the corresponding force that will be acted to the end point of the plant if the torques are applied.  $J$  is the robot's Jacobian. In the current implementation where the plant is located in a 2 dimensional workspace, the  $6 \times 3$  Jacobian matrix can be constrained to a  $2 \times 2$  matrix as:

$$J = \begin{bmatrix} -l_1 * \sin(q_1) + l_2 * \sin(q_1 + q_2) & -l_2 * \sin(q_1 + q_2) \\ l_1 * \cos(q_1) + l_2 * \cos(q_1 + q_2) & l_2 * \cos(q_1 + q_2) \end{bmatrix} \quad (7)$$

Each higher order force field from Fig. 2 is composed by summing and weighting the basis force fields from eq. 6. To find the weight coefficients, we form a system of  $N$  linear

equations by sampling  $M$  vectors  $P$  from the robot's operational space, for all  $B$  basis force fields.

$$\begin{bmatrix} \varphi_1^1(x^1) & \dots & \varphi_1^B(x^1) \\ \vdots & \ddots & \vdots \\ \varphi_1^1(x^M) & \dots & \varphi_1^B(x^M) \end{bmatrix} \begin{bmatrix} a_1 \\ \vdots \\ a_M \end{bmatrix} = \begin{bmatrix} P_1^1 \\ \vdots \\ P_2^M \end{bmatrix} \quad (8)$$

Each higher order force field is formed by summing and scaling the basis order force fields with the weight coefficients  $a$ . The vector  $a$  is obtained from the least squares solution to the problem:

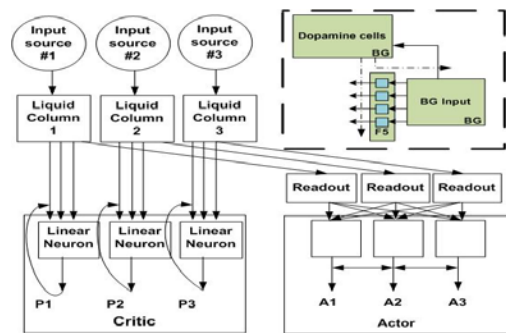

$$\Phi * \alpha = P \quad (9)$$

In the results section we show the force fields that are produced by solving the system in eq. 9, as well as how the plant moves in response to a higher order force field.

## Reward assignment pathway

One of the main methods of primate learning is by obtaining rewards from the environment. In the cerebral cortex, reward is associated with the secretion of dopamine, where approximately 80% of the dopaminergic neurons exist in the basal ganglia. One of the properties of these neurons is that they start firing when a reward is first presented to the primate, but suppress their response with repeated presentations of the same reward stimulus. At this convergent phase, the neurons start responding to stimuli that predicts a reinforcement, i.e. events in the near past that have occurred before the presentation of the reward.

In the early nineties, Barto (Barto, 1995) suggested an actor-critic architecture that was able to facilitate learning based on the properties of the basal ganglia. This architecture gave inspiration to several models that focused on replicating the properties of the dopamine neurons (see Joel et al., 2002 for a review). In the current paper we propose an implementation based on liquid state machines, and demonstrate how the interactions of this region with other neural networks of the brain can be modeled. The proposed implementation follows the actor-critic architecture and is shown in Fig. 4.

**Fig. 4.** The liquid state machine implementation of the actor-critic architecture. Each liquid column is implemented using a liquid state machine with feedforward delayed synapses. The critics are linear neurons, while the readouts are implemented using linear regression. On the top right of the figure (colored with green), we show how the actor-critic architecture is mapped on the model of Fig. 1.

The Critic neurons ( $P1, P2, P3$ ) model the dopamine neurons in the basal ganglia. Their role is to learn to predict the reward that will be delivered to the agent in the near future. The  $A1, A2, A3$  neurons learn based on the signal emitted by the Critic neurons. To model them in the current implementation we use a set of linear neurons. The liquid columns in Fig. 4 encode the input to the basal ganglia circuit. To implement the neurons in each liquid column we use the leaky integrate and fire neuron model:

$$\tau_m \frac{dV_m}{dt} = -(V_m - V_{rest}) + R_m * (I_{syn}(t) + I_{inject} + I_{noise}) \quad (10)$$

where  $V_m$  is the membrane voltage,  $\tau_m = C_m * R_m$  is the membrane time constant,  $R_m$  is the membrane resistance,  $C_m$  is the resistor capacitance,  $I_{inject}$  is a constant current injected to the neuron and  $I_{noise}$  a Gaussian random variable with zero mean and a small variance noise. After the emission of a spike, the membrane potential is reset to its resting value  $V_{rest}$ .  $I_{syn}(t)$  is the incoming current from the presynaptic neurons.

The connections between the neurons in the liquid are implemented using a model of dynamic synapses (Markram et al., 1998). The post-synaptic potential (PSP) of each neuron is transferred to its efferent based on the following equations:

$$PSP_n = L * R_n * u_n \quad (11)$$

$$u_{n+1} = u_n * e^{\left(-\frac{\Delta t}{\tau_{facil}}\right)} + U * \left(1 - u_n * e^{\left(-\frac{\Delta t}{\tau_{facil}}\right)}\right) \quad (12)$$

$$R_{n+1} = R_n(1 - u_{n+1}) * e^{\left(-\frac{\Delta t}{\tau_{rec}}\right)} + 1 - e^{\left(-\frac{\Delta t}{\tau_{rec}}\right)} \quad (13)$$

The maximum output of the synapse is governed by the absolute synaptic efficacy  $L$ . The change of the efficacy is determined using the variables  $u_n$  and  $R_n$ , which are calculated according to eqs. 12 and 13.  $u_n$  defines the utilization of the synaptic efficacy which decays exponentially based on the  $\tau_{facil}$  parameter to its resting value  $U$ .  $R_n$  is the fraction of available synaptic efficacy and defines the strength of the  $PSP_n$  at a given spike. It reduces due to the arrival of new spikes and recovers exponentially according to the  $\tau_{rec}$  parameter.

The actors, i.e. the cortical region that learns based on the predicted rewards of the critics is implemented using a set of linear regression readouts that are trained to output a firing rate proportional to the sum of firing rates of each liquid column. Input from different sources is modeled as a set of rate code neurons that each projects to a separate liquid column using linear synapses with zero delay.

To implement the synapses between the liquid columns and the  $P, A$  neurons, we use the imminence weighting scheme (Barto, 1995). In this setup, the critic must learn to predict the reward of the environment using the weighted sum of past rewards:

$$P_t = r_{t+1} + \gamma r_{t+2} + \gamma^2 r_{t+3} + \dots + \gamma^t r_1 \quad (14)$$

where the factor  $\gamma$  represents the weight importance of predictions in the past and  $r_t$  is the reward received from the environment at time  $t$ . To teach the critics to output the

prediction of eq. 14 we update their weights using gradient learning, by incorporating the prediction from the previous step:

$$v_t^c = v_{t-1}^c + n[r_t + \gamma P_t - P_{t-1}]x_{t-1}^c \quad (15)$$

where  $v_t^c$  is the weight of the Critic at time  $t$ ,  $n$  is the learning rate and  $x_t^c$  is the activation of the critic at time  $t$ . The parameters  $\gamma$ ,  $P$  and  $r$  are as in eq. 14. The weights of the actor are updated according to prediction signal emitted by the critic:

$$v_t^a = v_{t-1}^a + n[r_t - P_{t-1}]x_{t-1}^a \quad (16)$$

where  $v_t^a$  is the weight of the Actor at time  $t$ ,  $n$  is the learning rate and  $x_{t-1}^a$  is the activation of the actor at time  $t-1$ . In the results section we demonstrate how the output of the Critic neurons approximates the response properties of the dopamine cells discussed above, as well as how the actor neurons learn to control the higher order primitive model.

### Policy learning

Based on the higher order primitives and reward subsystems described above, the problem of reaching can be solved by searching for a policy that will produce the appropriate joint torques to reduce the error:

$$q_e = \hat{q} - q \quad (17)$$

where  $\hat{q}$  is the desired state of the plant and  $q$  is its current state. In practice we do not know the exact value of this error since the agent has only information regarding the end point position of its hand and the trajectory that it must follow in Cartesian coordinates. However because our higher order primitive model is defined in Cartesian space, minimizing this error is equivalent to minimizing the distance of the plant's end point location with the nearest point in the trajectory:

$$d_e = |l - t| \quad (18)$$

where  $l$  and  $t$  are the Cartesian coordinates of the hand and point in the trajectory, respectively. The transformation from eq. 17 to eq. 18 is inherently encoded in the higher order primitives discussed before.

From the output of the forward model we obtain the end point Cartesian location of the hand, while from the demonstrator we obtain the point in the trajectory that must be reached. These are injected as rate codes into a liquid state machine, where a readout neuron is taught to estimate the subtraction of the two input rates using a feedforward neural network.

The policy is learned based on two elements: (i) decide which higher order primitive force fields will be activated, and (ii) determine each one's weight. The output of the actor neurons described in the previous section implement the activation of the canonical neurons in the F5 premotor cortex which are responsible for gating the higher order primitives. Due to the binary output of the actor neurons, when a certain actor is not firing then its corresponding force field will not be activated. In contrast when an actor is firing, its associated force field is scaled using the output of the subtraction readouts, mentioned above, and added to compose the final movement.

To teach the actors the local control law, we use a square trajectory shown in Fig. 5, which consists of eight consecutive points  $p_1..p_8$ . The agent is taught the trajectory backwards, i.e. starting from the final location ( $p_8$ ) in four blocks. Each block contains the whole repertoire of movements up to that point. Therefore in the first block the actor learns to perform the left motion. Whenever it finishes a trial successfully, the actor is delivered a binary reward, and moves to the next phase which includes the movement it just learned and a new behavior.

**Fig. 5.** The initial trajectory used to train the robot. It consists of 8 points that form 4 perpendicular vectors in four different directions (up, right, down, left).

Reward is delivered only when all movements in a block have been executed successfully. Therefore, the agent learns to activate the correct force field primitives using the prediction signal from the Critic neurons in Fig. 4. The final torque that is applied on each joint is the linear summation of the scaled higher order primitives:

$$\begin{aligned} \tau_p &= [x_{e,1} * (J^{-1})^T * \varphi_{up}]_{act1} \\ &+ [x_{e,2} * (J^{-1})^T * \varphi_{down}]_{act2} \\ &+ [x_{e,3} * (J^{-1})^T * \varphi_{right}]_{act3} \\ &+ [x_{e,4} * (J^{-1})^T * \varphi_{left}]_{act4} \quad (19) \end{aligned}$$

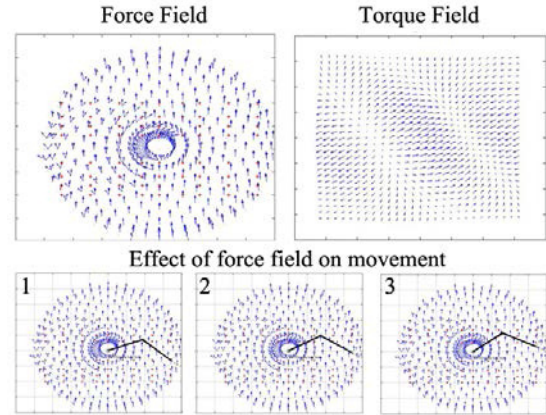

where  $x_{e,i}$  is the output from the neural network distance readout, while  $[ ]_{act}$  is an operator that includes each force field in eq. 19 only if the corresponding actor from the basal ganglia module is active.  $\varphi$  is obtained from eq. 6 for each higher order force field, and  $J$  from eq. 7.

## Results

In the current section we present the results of the proposed model. We focus on the training of each pathway, as well as the model's ability to follow various different trajectories.

The first result we consider is the convergence of the least squares solution for the system of linear equations in eq. 9. Figure 6 presents the solution for the “up” higher order primitive, where it is evident that the least squares algorithm has converged to a good result. The three subplots at the bottom illustrate how the hand moves towards the “up” direction when this force field is active. Similar solutions were obtained for the other three primitives, where the least squares solution converged to 7 (left), 2 (right) and 5 (down)

errors (the error represents the average deviation of the vectors in a field from the correct direction of the force).

**Fig. 6.** The force field (upper left subplot) and torque field (upper right subplot) as converged by the least squares solution for the “up” primitive. The three subplots at the bottom show how the hand moves when the primitive is active.

The policy for reaching was learned during the initial imitation phase described previously. During this phase the robot performed the training trajectory, and was delivered a binary reinforcement signal upon successful completion of a whole trial.

Since the reward signal was only delivered at the end of the trial, the agent relied on the prediction of the reward signal elicited by the critic. In the following we look more thoroughly on the response properties of the simulated dopaminergic critic neurons and how the actors learned to activate each force field accordingly based on this signal.

Figure 7 illustrates how the critic neurons of the model learned to predict the forthcoming of a reward during training. In the first subplot (first successful trial) when reward is delivered at  $t=4$ , the prediction of the 1<sup>st</sup> critic is high, to indicate the presence of the reward at that time step. After the first 10 successful trials (Fig. 7, subplot 2), events that precede the presentation of the reward ( $t=3$ ) start eliciting some small prediction signal. This effect is more evident in the third and fourth subplots where the prediction signal is even higher at  $t=3$  and starts responding at  $t=2$  as well.

**Fig. 7.** The prediction signal emitted by the critic component of the model during the initial stages of the training (subplot 1), after 10 trials (subplot 2), after 20 trials (subplot 3) and after 30 trials (subplot 4).

The effects of this association are more evident in Fig. 8, where it is shown that, after training, even though rewards are not available in the environment, the neurons start firing because they predict the presence of a reward in the subsequent steps. Using the output of this prediction signal,

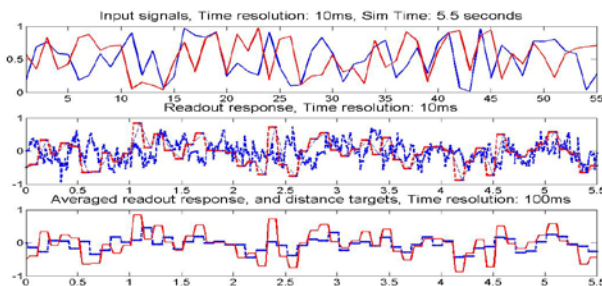

the actor, i.e. in the case of the model the F5 premotor neurons that activate the force fields in the MI, forms its weights in order to perform the required reaching actions.

**Fig. 8.** The actual reward signal given to the robot at the end of a successful trial (upper subplot), and the reward predicted by the critic component after training (bottom subplot). The x-axis represents the 100ms time blocks of the simulation while the y-axis the values of the reward and prediction signals respectively.

The second part of the policy is for the model to learn to derive the distance of the end effector location from the current point in the trajectory. This is accomplished by projecting the output from the forward model and perception pathways in an LSM and using a readout neuron to calculate their subtraction. Having run several different simulations we found that to shape the liquid dynamics and learn this transformation the dynamic synapses must have delays of approximately 10ms. Since our model resolution was set to 100ms, we averaged the output of the readout neuron over the 10 steps of the simulation. In Fig. 9, we illustrate two sample signals as input to the liquid (top subplot), the output of the readout neuron in the 10ms resolution (middle subplot) and the averaged over the 100ms of simulation time output of the readout neuron (bottom subplot).

**Fig. 9.** The output of the distance LSM after training. The top plot illustrates two sample input signals of 5.5 seconds duration. The bottom two plots show the output of the neural network readout used to learn the subtraction function from the liquid (middle plot), and how this output is averaged using a 100ms window (bottom plot).

The whole simulation trial lasted 5.5 seconds. As the results show the liquid was able to extract the distance information with a good accuracy. Due to the local control laws used to implement the reaching policy, any small errors in the computation of distance are actually compensated in later steps.

Having established that the individual pathways/components of the proposed model operate successfully, we now turn our attention to the performance of the model in various reaching tasks. We note here that the model wasn't trained to perform any of the given reaching tasks, apart from the initial training/imitation period at the beginning of the experiments, shown in Fig. 5. After this stage the model was only given a set of points in a trajectory and followed them with very good performance. The first three trajectories we tested were variations of a straight line motion.

**Fig. 10.** Three trajectories shown to the robot (red points) and the trajectory produced by the robot (blue points). Numbers mark the sequence with which the points were presented.

As Fig. 10 shows the agent was able to follow all three trajectories quite precisely. The average normalized deviation of the agent's position from the points of the trajectory was 0.03 which shows that the resulting performance was satisfactory.

In order to evaluate further the performance of the model we used two more complex trajectories. The first required the robot to reach towards various random locations spread in the robot's workspace (Fig. 11, Trajectory 1) while the second complex trajectory required the robot to perform a circular motion in a cone shaped trajectory (Fig. 11, Trajectory 2). Figure 11 illustrates how the aforementioned trajectories were followed by the robot.

**Fig. 11.** Two complex trajectories shown to the robot (red points) and the trajectories produced by the robot (blue points). Numbers mark the sequence with which the points were presented.

To evaluate the performance of the model on any given path we created 100 random trajectories and tested whether the agent was able to follow them. Each of these random movements was generated by first creating a straight line trajectory (Fig. 12, left plot) and then randomizing the location of 2, 3 or 4 of its points; an example is illustrated in Fig. 12, right plot. The error was calculated by summing the overall deviation of the agent's movement from the points in the trajectory for all the entries in the dataset. The results indicate that the agent was able to follow all trajectories with an average error of 2%. This suggests that the selected model can confront with high accuracy any reaching task.

**Fig. 12.** The template used to generate the random test set of 100 trajectories (left plot) and a random trajectory generated from this template (right plot).

## Conclusion

One of the important aspects of human skills is the ability to generalize knowledge to different domains and tasks. Using modularity and principles from neuroscience, in the current paper we investigated how adaptive learning skills can be acquired in a simulated agent that performs reaching tasks. One of the extensions that we plan for the presented model is to investigate how the primitive model can be designed to be adaptive, i.e. allow the agent to match the control of primitives to the properties of its body. In addition we will extend the current 2D plant model to its 3D equivalent by adjusting the equations of the Jacobian and primitive model. Moreover, we plan to investigate the role of the cerebellum in reaching movements, and its involvement in providing corrective feedback in respect to the global error of movement. Finally one of the important additions that we plan to investigate is how the agent developed in the current paper can be used during observational learning, i.e. improve its performance in reaching tasks without using its body. This extended model will be used to evaluate certain hypotheses regarding whether learning can be implemented in primates during observation.

# Energy as a driver of diversity in open-ended evolution

Tim Hoverd<sup>1</sup> and Susan Stepney<sup>1</sup>

## Abstract

We investigate the consequences of introducing an energy model into open ended evolutionary simulations. We propose a metamodel for simulations that incorporate an energy model and apply that model by extending Turk's *Sticky Feet* model. We show that introducing an energy model produces simulations with measurably increased diversity of the simulated population.

## Introduction

We are interested in open ended evolution and in particular evolution within systems that are open to a simulated energy flux, open to changes in the simulated environment, and open to the representation of evolutionary mechanisms. In this paper we focus on energy flux, which allows us to represent many aspects of real world systems, such as the availability of food supplies, and different means of making a living within an environment, be they predatory or sessile.

In order to investigate these issues we have chosen to extend Turk's *Sticky Feet* [10] model. This gives a simple mechanism for implementing mobility and experimenting with open-ended evolution. A *Sticky Feet* simulation is a collection of simulated creatures moving in a 2D domain. Each such creature is a graph of *springs* connecting together *feet*. Motion is achieved as a consequence of simple harmonic oscillation of the springs, which pushes the feet around within the simulation space. The coefficient of friction experienced by the feet is modulated—at times slippery, at times sticky—which results overall in motion through the space.

Each creature has a heart and a mouth, each of which is a distinguished type of foot. The heart represents the creature's 'essence'. The mouth—when it happens upon another creature's heart—allows the former creature to eat the latter, removing it from the simulation. The likelihood of a creature happening upon another is facilitated to some extent by the springs being equipped with sensors, which may modulate the oscillation of the spring when in the presence of another creature's heart. This allows a creature to turn towards another, with the chance that it might then be able to

consume the target. When a creature is consumed the eater produces a single offspring, which may be a mutation of the parent. Mutations that include additional feet, springs and sensors allow the creatures to evolve in a manner that eventually produces offspring that are better adapted to hunting for and eating other creatures.

A *Sticky Feet* world is one in which creatures evolve to improve their performance at consuming other creatures, and therefore being able to pass on their genome. As such, it provides some aspect of a model of open ended evolution. We use this term here in the sense of an evolutionary system where components continue to evolve new forms continuously, rather than halting when some 'optimal' or stable position is reached [9].

*Sticky Feet* [10] works in this manner, as there is no overall fitness function and all creature behaviour is expressed in a single large environment rather than relying on artificial two-creature tournaments. As such it is representative of many aspects of real-world evolution.

There is, though, no mechanism for sticky feet creatures to pass on their genomes other than by consuming other creatures. That is, the simulation is closed to the development of non-predatory behaviour. This is useful from the point of view of maintaining a constant sized simulation, but is not representative of real world evolution where population sizes can change dramatically.

Natural evolution—that which operates in the world around us—is different in essence from the sticky feet model in that success does not entirely derive from hunting and reproduction. Creatures in natural environments must be able to extract some sort of living from that environment, supported either by consuming other creatures, or by turning some flux in the world, for example sunlight or the chemical nutrients consumed by extremophiles, into food.

This argument is essentially that famously made by Malthus in 1798 [7], which led Darwin towards the principle of natural selection [2]. Although Malthus discussed the availability of food we generalise this to the availability of *energy*. This is a limited resource although the environment is continually bathed in an energy flux. This flux may

Figure 1: Domain metamodel

be used, and stored, by components of the environment, but if it is ignored it disappears and is no longer of use.

Natural systems are open: they are in receipt of some sort of resource flux such as that we model as energy. In this paper, we provide a meta-model for open simulations with energy flux, consumption, and storage; we describe an extended sticky feet simulation incorporating an instantiated energy model; we show that diversity is maximised when the flux is neither too low, nor too high.

## Energy metamodel

In our work we use the CoSMoS approach [1]. We model the aspects of the domain that we wish to simulate as the *domain model*. We describe the actual simulation using the *platform model*, which executes on the *simulation platform*, producing results that can be analysed with respect to the *results model*.

In this paper we describe a *class* of models, ones that permit a particular sort of open ended evolution of sticky feet like creatures in a world, a domain, which is bathed in an energy flux. That is, we must define a *domain metamodel* to which our domain models must conform.

The domain meta model describes all possible domain models that we wish to explore, without limiting the particular domain. An abstract view of our meta-model is shown as figure 1<sup>1</sup> and shows the inter-dependencies of the three top level packages in our model: *Organism*, *Energy* and *Environment*.

## Energy

Energy is modelled, as in figure 2, as a scalar quantity in arbitrary units. We also describe the *entropy* of some energy which might be thought of as the temperature of the energy which allows us to describe essential aspects of the energy economy. For example, in the natural world a continuous low flux of low entropy energy is available in the form of sunlight. Plants sequester this energy in a form that allows other organisms, such as animals to consume them and acquire the stored energy. Those animals subsequently excrete waste products which still represent energy, albeit in

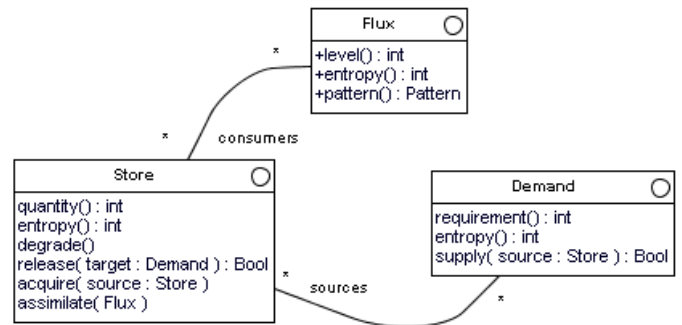

Figure 2: Energy metamodel

Figure 3: Environment metamodel

a higher entropy form, but which may still be metabolized by organisms such as dung beetles.

Although some authors use a simple "battery" model or conservation of energy (for example [3]), here we propose an energy model integrated with reproduction and behaviour.

**Flux.** The most basic part of the energy model, representing a flow of energy from outside the modelled system. This flux represents energy with a defined entropy and with a particular temporal pattern; for example at a high level during daytime but a much lower level during nighttime.

**Store.** One action of all members of a simulated world is to store energy. An organism might maintain its existence by consuming other stores, in the manner of herbivores eating plants, or by assimilating the flux itself as the plant itself does.

**Demand.** Many components of a simulated world make energy demands. Such components could be the physical structure of an organism, which requires energy to build and maintain, or an activity that an organism undertakes, such as hunting for other organisms to consume.

## Environment

The environment metamodel is elaborated in figure 3.

<sup>1</sup> All the models here are expressed using the UML.

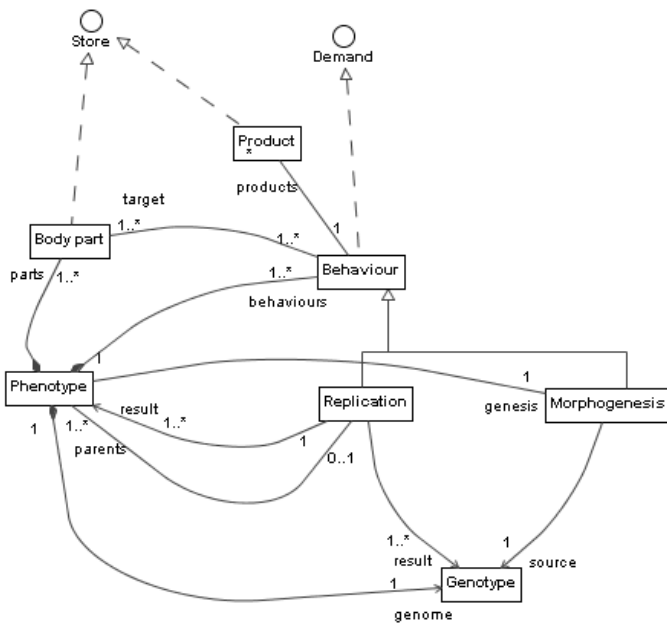

Figure 4: Organism Metamodel.

Environments are represented as a collection of Regions, each of which is the recipient of a particular Flux. Regions are connected together by routes each of which allows organisms to move from one region to another, albeit at a certain energy cost.

## Organism

The organism metamodel is elaborated in figure 4<sup>2</sup>. It has two interdependent components: the phenotype and the genotype.

**Genotype.** The Genotype metamodel requires that an organism model expresses a genotype, which can be used as the source information for a morphogenesis process that grows its associated Phenotype. The genome of a phenotype is the result of a replication process that also creates a new Phenotype.

**Phenotype.** The Phenotype metamodel expresses that an organism's phenotype, its structure, consists of a number of *body parts* and a number of *behaviours*.

Body parts store energy: they realise the Store component of the energy model. The body parts are also the *target* of the organism's behaviours. For example, a bird's wings might be the target of its 'flying' behaviour. Each behaviour affects at least one part of an organism's body, and all such parts must be such a target of at least one behaviour.

Behaviours consume energy: they realise the Demand component of the energy model. We require that all energy

consumption is expressed as a behaviour. So, for example, a purely sessile organism must still include a behaviour that it continually expresses, which demands the energy needed to maintain its metabolism. The energy for a behaviour is supplied by the body parts that are the target of the behaviour.

Some of an organism's behaviours produce waste products, included as the *Product* component. Such waste products are in themselves further energy stores, although they are not part of the organism's phenotype. The entropy of such waste products would usually be higher than that of the original energy source, but that does not preclude some organisms being able to scrape out an existence using such low grade sources of energy. A further waste product is the phenotype of a dead creature. Again this represents a low-grade source of energy, providing carrion-eating as a possible way of making a living in a world that conforms to our model.

All organisms possess the *Morphogenesis* behaviour; the genome contains the information needed for this behaviour. The specific genome of an organism is the result of another behaviour, *Replication*, which creates the genome of an offspring organism, potentially generating a mutated genome.

## Discussion

Our metamodel expresses the essential requirements for evolution in an energetic context. A range of different implementations of this model are feasible. That is, a number of models could be produced, each of which conformed to this metamodel in the sense that the model's components were instances or realisations of components in the metamodel. Each such model would describe the domain model for a particular set of simulations in a particular domain.

Note that some ALife simulations incorporate a very basic notion of a constrained resource. Tierra [8] uses CPU time-slices as an analogue of energy, with the size of the time slice being a tunable function of the entity's size. However, there is no analogue of an energy store that would enable entities to 'time-shift' their use of the resource, or hand on a surplus to their progeny; Tierra is a 'use it or lose it' model. (Ray [8] mentions a possible extension allowing capture of CPU slices.) Stringmol [5] is an AChem with an explicit, but very simple, energy model: a fixed number of energy units are added to the container at each timestep, and molecules need to use an amount to execute each instruction. However, the energy is a global resource (energy is not stored in individual entities, but in the system and accessible to all). Our rich energy metamodel provides a number of features that organisms should be able to exploit to enable a range of different ways of making a living.

## Energetic sticky feet

We have developed one simulation model (figure 5) that conforms to our energy metamodel. This is an 'energetic' variant of Turk's Sticky Feet [10]. That is, our energetic sticky feet model discusses the same sort of concepts that Turk

<sup>2</sup>The arrowheads in this diagram refer to the UML property of *navigability* not to a notion of one object "producing" another.

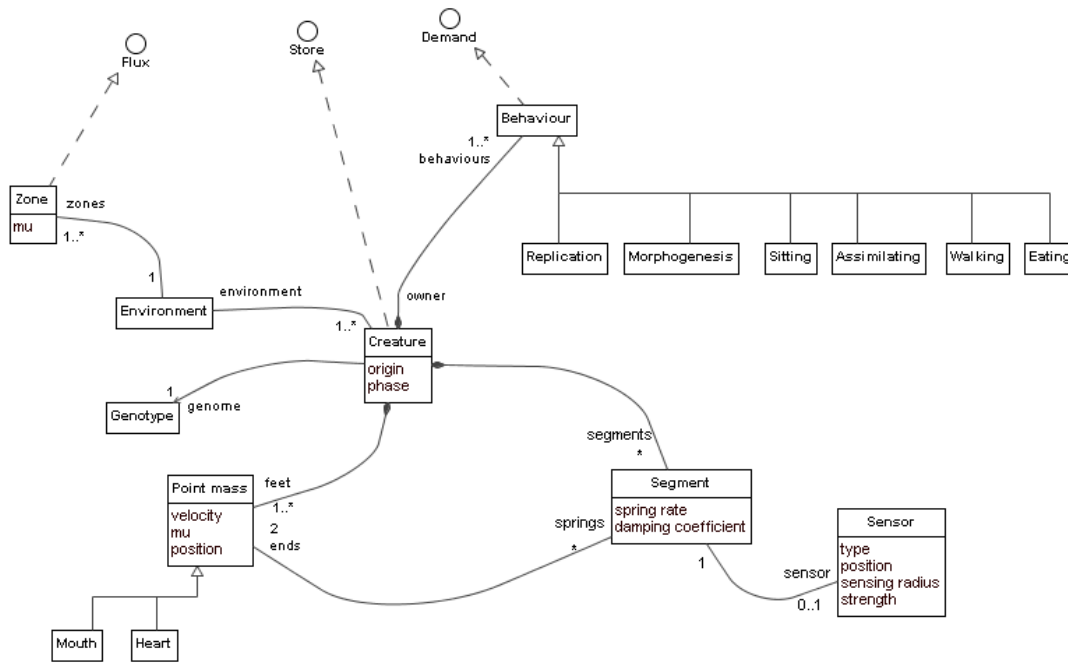

Figure 5: Energetic sticky feet overview

uses, albeit in the context of energy, environment and organism as prescribed by our metamodel.

Our experimental hypothesis is that the presence of the energy model will influence the evolution of the simulated creatures in such a manner that a more diverse world will result. We test this hypothesis by running the energetic sticky feet simulation for a range of flux levels, and compare the diversity of the evolved creatures with an unconstrained variant that ignores the need for energy.

## Body parts

The creatures in our model follow the metamodel: each creature has a number of parts and a number of behaviours. The specific body parts are *feet* and *segments*. Following Turk [10]: a foot is a point mass with a particular, and modulatable, coefficient of friction; a segment is a spring that follows the equations from [10], to achieve motion due to simple harmonic oscillation of the springs as the point masses' coefficients of friction are varied.

The feet themselves appear in three varieties. The basic ones are augmented with special variants, representing a heart, and a mouth. The heart represents the 'essence' of a creature. When one creature's mouth gets close to the heart of another creature then the former may 'eat' the latter (assuming that the former creature is expressing the 'eating' behaviour).

Each segment may optionally have an attached sensor, which senses the position of other creatures. A sensor may sense either the heart or the mouth of another creature and, when it does, may perturb the oscillation of its attached seg-

ment. In this manner the sensors allow a creature to turn towards prey, or away from a predator.

## Behaviours

The overall behaviour of each creature is represented by attaching a collection of individual behaviours to the creature. Each of these acts in a manner reminiscent of the *Command* pattern [4], and applies itself if it determines that the time is appropriate. Every behaviour demands energy, which must be provided by the owner of the behaviour. If the owner cannot supply the energy then the creature dies: it has exhausted its energy supplies.

Our energetic sticky feet implementation does not implement the waste product component of the metamodel. Consequently, when a creature dies, it just disappears from the simulation, taking with it any residual energy.

The behaviours available to a sticky creature are:

**Sitting:** the 'null' behaviour that all creatures must express. This behaviour forces a creature to continually consume energy. The amount of energy consumed is a function of the complexity of the creature's phenotype; a larger, more complex, creature requires more energy just to sit in one place compared to a small, simple, creature.

**Walking:** the behaviour that expresses the mode of walking explored by Turk [10], by oscillation of the creature's segments. The size of the energy requirement is proportional to the friction against which work is done by the springs.

**Eating:** the behaviour that allows a creature to look to see if any other creature's heart is in the vicinity of one of its mouths. If so, the former creature may 'eat' the latter. This adds to the eating creature's energy stores all of the energy of the eaten creature. The eaten creature is removed from the simulation.

**Reproducing:** the behaviour that allows a creature to create offspring, with a genome that is a mutation of the single parent's genome. At each simulation step there is a probability, encoded in the genome, that a creature may express this behaviour. We allocate energy costs to all the components of the phenotype, and check that the parent has sufficient energy to construct the child organism. If so, and the child organism is deemed to be viable, then it is created and the energy store of the parent is shared equally between the parent and the child.

**Morphogenesis:** the behaviour that is followed to construct the phenotype of a new organism from the genome generated by, optionally, mutating the genome of the organism's parent. This differs from the Reproducing behaviour in that it is responsible for building the phenotype of the organism from its genome whereas the reproducing behaviour creates the new organism's genome.

**Assimilating:** the behaviour that allows an organism to gather energy directly from the flux in the current environment. The amount of energy available is determined by the flux applied to the region of the environment that the creature is inhabiting, and by the physical size of the creature. A larger creature, in the same manner as a large tree, can extract more energy from the flux, but needs correspondingly more energy to construct and maintain the larger phenotype.

## Mutation and morphogenesis

In order to get some sort of evolution of the sticky feet creatures our implementation allows for mutation of the genome whenever the reproducing behaviour is expressed. Mutation is implemented by structuring a genotype as a sequence of genes, each of which codes for a particular part of the creature and its behaviour. Unlike Turk [10] we do not express a 'species' in any way in our model. Rather, each organism just has its own genome; even though it is likely that many other creatures have the exact same genome we do not use this in any part of our simulation. Following Turk's lead we implement two general forms of mutation, both of which are used in any individual mutation step. The first of these is the modification of the various parameters that apply to each component. For example this allows the position of the creature's feet, the stiffness of the springs in the segments, and the probability that a creature will attempt to express the reproducing behaviour at any particular point in time to be varied. The second form represents structural modifications of the phenotype. Specifically, these modifications may be

Figure 6: Some example evolved creatures; the filled circle is the heart, the open circles are mouths. From left to right these are: a) the initial 'seed' creature; b) the 'manta ray', only a few mutations away from the seed; it has two mouths; c) the 'killer', large and fast; d) the 'multimouth', with lots of mouths that stab outwards; e) the 'spiky', with lots of mouths but little area.

performed: adding feet or segments, removing feet or segments, adding a sensor to a segment and modifying a segment so as to connect to a different foot.

A possible result of one or more of these mutations is that the eventual creature does not form a viable phenotype. For example, it is possible to generate a genome that implies a phenotype where the feet and segments are not connected as a single structure, or where a creature does not have a heart. We choose to declare these mutations non-viable, and terminate the particular cycle of reproduction when they occur.

Even if a mutation represents a viable creature, it is possible that the resulting creature cannot be incorporated into the current simulation world. Specifically, in a similar manner to Turk, we do not allow phenotypes that initially overlap existing creatures. That is, our simulations are expressly two dimensional at the moment.

Viable creatures are created at a point in the simulation space that is local to their parent.

## Implementation

Our energetic sticky feet implementation follows closely the model shown in figure 5. The implementation is written in pure Java and uses our environment-orientation approach [6] to represent the interaction of many creatures in a multi-threaded implementation. The environment is a two dimensional world with cyclic boundary conditions.

In all our experiments we initialise a simulation run with a fixed number of simple 'seed' creatures with a pre-defined genome and a random (according to a Gaussian probability distribution function) amount of energy. A typical collection of evolved creatures is shown in figure 6.

There are a large number of parameters to our sticky feet simulations. For example, there are parameters describing the construction energy required for each part of an organism, for the rate of mutation and for the level of energy flux in different regions of the environment.

Initial experiments with our implementation show that careful setting of these parameters is necessary in order to

allow the creatures to survive. That is, it is very easy to set the parameters so that there is insufficient energy in the environment for a population of creatures to survive; even though they can mutate to take advantage of their environment they run out of time in which to do so. This is in some ways perhaps a consequence of our approach of seeding the environment with a collection of fully formed creatures with significant energy demands.

## Experimentation

In order to compare our simulations with something more representative of Turk's implementation [10] we need a way of 'turning off' the energy model. That is, we need to be able to run simulations in a manner that is not constrained by the availability of energy. In Turk's implementation the simulation has a fixed size population as a consequence of each creature reproducing once only when it consumes another. Hence, the simulation world does not get overrun with a vast number of creatures.

In a similar manner, our simulation includes an 'unconstrained energy' option where the creatures function exactly as they do in the energetic world except that the *demand* of all behaviours is set to zero, so no energy is ever consumed, and the *reproducing* behaviour is only available, and indeed is forced, in the situation where the *eating* behaviour has been invoked. This has the effect of creating a fixed-population simulation (except that on occasion a new creature cannot be 'fitted in' to the existing simulation, in which case reproduction is delayed until space is available) of a form similar to Turk's.

The differences between the implementation of the 'energetic' and 'unconstrained' variants of our simulation are minor. Hence, we can be sure that measured differences in the results of the simulations are a consequence of the inclusion, or exclusion, of the energy model.

In order to track the develop of creatures as they evolve we use a notion of *mutation distance* in our experiments. As discussed we have no specific notion of 'species' in our implementation. Rather, each creature has its own genome, which has a mutation distance. The initial population of creatures all have a copy of the same genome, which has *mutation distance* = 0. Whenever a creature reproduces it may also mutate the genome which is passed on to the child creature. The likelihood of allowing such a mutation is one of the simulation's parameters. After this mutation, following the process described earlier, the implementation compares the resulting genome with the initial genome. If they are different (they might not be because of the random nature of choosing whether to adopt specific mutations) and the genome represents a viable creature, then that new genome mutation distance is incremented.

In this manner every creature has a mutation distance, and we use this as part of our experimental results. There is not a simple relationship with *time*; it is possible, although un-

likely, for example, for a creature with mutation distance 150 to co-exist in a simulation with another of mutation distance 0. The latter creature could have survived from the outset—our creatures do not die of old age—or it could be the end result of a series of reproductions that involved no mutations.

Each creature in our simulations has an *area* that determines the amount of energy it receives from the environment's energy flux. We calculate its area by regarding the creature as an irregular polygon, ignoring feet that have only one attached segment, and by calculating the area of that polygon. So, a creature that was two feet connected by a single segment (a frequently occurring shape) would have  $area = 0$  and would not receive any energy from the environmental flux.

## Hypotheses

The direction of our experimentation is towards investigating two hypotheses. First, we hypothesise that creatures evolving in the context of an energy model should do so in a manner that is measurably different from that which applies in a 'unconstrained energy' world. Second, we hypothesise that the presence of the energy model creates a wider range of ways of the sticky feet creatures 'making a living'. For example, a creature could survive by eating other other creatures, or it could survive by growing large enough to acquire sufficient energy from the regional flux. Such a mode of life could be further enhanced by abandoning movement as that could be seen as wasting precious energy. Hence, we hypothesise that when evolving in the presence of an energy model the sticky feet creatures will appear in a wider range of sizes during their evolution than happens in an 'unconstrained energy' world.

Similar hypotheses could be expressed about other physical aspects of the creatures. Here we explore just the size.

## Results

Our simulations generate a large quantity of data and here we show just a single summary of one aspect of it. Figure 7 shows a plot of the inter-quartile range of the sizes (areas) of the population of creatures as it changes with the genome mutation distance. This figure includes data for three different configurations: the unconstrained 'control' situation, one with an energy flux of 80 (arbitrary) energy units, and one with an energy flux of 100 units. Data for this plot are taken from a total of over 40 separate simulation runs and summarise the simulated lives of over 350,000 energetic sticky feet creatures.

We have chosen these energy levels based on experience running our simulations. Below an energy flux of 80 units it is invariably the case that the population of creatures dies out. For example, in all our experimental data no creature has existed in a simulation with a flux of 70 with a higher

Figure 7: Summary of results of execution of energetic sticky feet simulation with mutation distance on the X axis. The foreground, darkest, distribution shows the inter-quartile range of the areas of sticky feet creatures across 200 mutation distances of evolution using the implementation that did not use an energy model. The mid-grey plot is the same information using the energy model at a flux level of 100 units. The pale grey plot shows the results using the energy model at a flux of 80 units.

mutation distance than 94. At a flux of 50, we see nothing beyond mutation distance 73.

Even without comparing the data with the unconstrained situation we see a clear effect of the flux on the simulated lives of the sticky feet creatures. Furthermore, inspection of figure 7 shows significant differences between the ‘with energy’ and ‘unconstrained energy’ variants of our simulation. For example, at mutation distance 200 (the largest we show on the figure) creatures in the *energy* = 80 world have a range of sizes from 280 area units at the lower quartile to 2170 units at the upper quartile. In the ‘unconstrained energy’ world the equivalent sizes are from 140 to 238 units.

Experience with our experiments, and observation of the results shown here, leads us to a further hypothesis. This is driven by the observation, seen in figure 7, that at *energy* = 100 there is less population diversity than at *energy* = 80. As we know that at lower energy levels the populations of sticky feet creatures usually dies out we hypothesise that there is a critical energy flux density, in a set of simulations with otherwise consistent parameters, that generates creature populations of the widest diversity. At low energy levels there is insufficient energy for populations to survive and hence they die out before generating significant diversity; at higher energy levels it becomes easier and easier to make a living, all the way up to the unconstrained world.

We choose a single statistic to represents diversity of simulations with a particular energy flux, and look to see if it varies in the hypothesised manner. The statistic we use is the range of sizes of creatures throughout all lifetimes at a particular energy level. Figure 8 is a box and whisker plot

of the interquartile range (IQR) of sizes of creatures over all mutation distances. In figure 8, the median represents the median IQR of sizes over mutation distance at a particular energy flux (the median size of the bars in figure 7): the larger the median, the larger the range of sizes, hence the greater the diversity. In figure 8, the IQR represents the variation in the IQR of sizes over mutation distance at a particular energy flux (the range of sizes of the bars in figure 7): the larger the IQR in figure 8, the larger the range of range of sizes, hence the greater the range of diversity. Observation of figure 8 does indeed show the hypothesised characteristic of a critical energy flux with maximum diversity.

## Discussion

The hypotheses that we have discussed are supported by the experimental results we have included. Specifically, the results we see when running the ‘energetic’ simulations show a more diverse range of creatures being produced than in similar ‘unconstrained energy’ situations. Furthermore, there is a ‘critical’ energy level that supports the widest diversity. At lower energies we see less diverse populations that soon die out; at higher energies—which includes the unconstrained case—we see less diverse populations that nonetheless persist. The critical energy level is the point between a low energy world where eating other creatures is a necessity of life, but nevertheless there is not enough influx of energy to survive, and a high energy world where there is little evolutionary pressure, and sessile behaviour is common.

Visual inspection of our simulations make it painfully

Figure 8: Box plot of inter-quartile ranges of creature sizes at various energy levels. Each plot shows the 9th percentile, the first quartile, the median, the third quartile and the 91st percentile for the distribution of the inter-quartile ranges at the given energy flux. The rightmost box is for the unconstrained energy version of the simulation.

clear that although we generate creatures with a wide range of sizes and structure they are still recognisably the same sort of thing: variations on a theme of feet and springs (figure 6). The end result is interesting but does not compare with biological evolution and the vast range of forms and structures that we see there. Our simulations could never generate such a range of structures because the creatures' representation, morphogenesis and mutation operators are fixed, even though the various probabilities of their application and effect may change. That is, although we have a general notion of the sorts of energy we are simulating, and this is encoded in our metamodel, we do not have a similar notion of a range of organisms. Therefore, the evolution we are exploring here is not fully open-ended. In order to do that we need a more abstract description of evolution.

## Conclusions

Our metamodel summarises the essential components of an energy-rich world which is a basic feature of real world evolution, and also of artificial life. We have shown that application of this metamodel in even a simple manner yields more complex, more interesting, results.

However, our experiments also make it obvious that we need much more in order to approach real open-ended evolution. In particular we must be able to modify both the creatures and the kinds of modifications that the creatures undergo. Our current simulations do not support this.

## Future Work

While interesting, our current simulation does not explore some aspects of the worlds implied by our metamodel. In

particular we have not explored the notion of entropy, which we believe should open up further different ways of creatures making their living. We have also not explored a non-homogeneous world with, for example, a range of different energy fluxes and different levels of friction which could make, again, different modes of existence feasible.

And, as we have discussed, we would like to investigate ways of extending the kinds of evolution that occur in order to more closely approach true open-ended evolution.

## Abstract

Autonomy of the internet (web system) is studied by running an NS-2 simulator. A web system consists of three layers, they are the network, the transport and the application layer and an network simulator called NS-2 can simulate the transport layer of the web as a packet switching network (PSN). This paper reports on the complexity of mutually crossing packet flows which are comparable to other autonomous complex networks, such as real Hippocampus slices, Izhikevich neural networks, or the game of life. One unique feature common in all these systems is the coexistence of several synchronised patterns that we think of as the underlying mechanism of autonomy. In the case of PSNs, adaptive window sizes of each packet flow show synchronisation but only locally, and often chaotic behavior is displayed when congestion occurs. Also considering the packet flow in PSNs as gliders, this congestion allows gliders to bifurcate. We thus propose PSNs as a new experimental testbed for discussing the autonomy and adaptability of living systems.

## Introduction

Autonomy is one of the most important characteristics of living systems. Understanding this biological autonomy by reconstructing it using different media is one of the main purposes of Artificial Life studies. For example, the study of autonomous robots uses such an approach. A definition of an autonomous robot is its ability to achieve a task without people having to make commands. There are many examples such as Stefano Nolfi's 'garbage collectors' (Nolfi, 1997), Pfeifer's passive dynamic walker (Pfeifer et al., 2007), Honda's 'Asimo', Sony's 'dog robot' called Aibo, Kojima's 'Keepon' and so on. Some of these robots are "autonomously" detecting walls and avoiding cliffs in various ways. Self-charging robots have also been built already (e.g. a robot that uses snails for energy or a trilobite-like robot that monitors its own battery); so robots can become self-sustainable in that sense.

Rodney Brooks claimed that autonomous robots need not possess any representation of the environment but the environment itself is the representation. They explore the environment and solve a given task. This is a major feature of autonomous robots (Brooks, 1991). Such a concept of

autonomy still misses a very fundamental part of biological autonomy, as we are still easily able to distinguish between real and artificial creatures (Brooks, 2001).

A simple but primary definition of an autonomous system is a non-reaction system. For example, a fly's aviation is considered to be an autonomous behavior as it behaves independently from the environmental pattern (May et al., 2007; Takahashi et al., 2008). Another such autonomous dynamic is chaotic itinerancy (Ikegami, 2007); a high dimensional transition dynamic among pseudo attractors. Aoucuturier et al. (Aoucuturier et al., 2008) used this idea to create a dancing mobile robot. Besides a hard-shell robot, Hanczyc and Ikegami (Hanczyc et al., 2007; Hanczyc and Ikegami, 2010) studied a self-moving droplet. An oil droplet made of oleic acid and sized about 0.1 mm can move by itself and also react to environmental pH.

The underlying principle in all these examples is that an interaction between a system and its environment creates autonomy. In other words, a system can generate and maintain its own context which temporarily couples and decouples with the environmental context. More importantly, a system has its own dynamics without requiring an externally given task. A so-called 'default network' found in a brain's resting state is another example of such autonomy (Raichle et al., 2001). The definition of a default network is the brain activity observed while people are day-dreaming or doing non-specific tasks. A global (non-periodic) synchrony in neural activity was found to exist in the default network.

In this paper, we discuss the concept of autonomy using the example of web systems. Nowadays, web systems have become huge and complex enough to have consciousness-like states. Such web autonomy can be considered sufficiently close to biological autonomy. Corresponding to the non-periodic neural synchrony found in the default network, we will report the non-periodic behavior in a simulated web system.

In §2, we review the constitution of web systems, and in §3, we introduce an internet simulator called NS-2<sup>1</sup> which emulates the packet switching network (PSN) of the inter-

Table 1: Comparison of five different network systems is be conducted; a real brain system, the internet, artificial neural nets (ANN) and the game of Life. The structure and dynamics of each network is depicted in the 2nd and 3rd row, respectively. Possible dynamics of the internet in terms of PSNs is discussed in this paper. In the 4th row, kinds of memory in each network is also described, where an ANN stores its memory in terms of attractors and chaotic itinerancy (CI) and the game of life stores its memory in terms of special spatial configurations.

net’s transport layer. In§4, data from the NS-2 simulation will be discussed with respect to dynamic stability. In §5, a simple question we can ask about the web autonomy such as ”what happens if everybody stops accessing the internet”, is examined. Finally, we will discuss what brings autonomy to a PSN.

### Web Systems

The internet has made great progress in the last 20 years and it has become a lifeline for human society. Its structure consists of roughly three layers; a network, a transport and an application layer. When studying the autonomous dynamics of the internet’s application layer, we can examine web crawlers and Google’s PageRank to see how the database is automatically organised and ranked. Many social network services (SNSs) such as Twitter are also worth noting. They mutually copy and reproduce personal timelines in massively parallel ways which is somehow complementary to what Google’s service is processing on their stored data.

On the other hand, what enables Google and Twitter to function correctly is a PSN on the transport layer and its backbone network layer. This creates a system that can be mutually connected on the internet with IP addresses on the network layer. The protocols used for communicating among those IP addresses are TCP or UDP. In particular, TCP is equipped with relatively intelligent software. Each network router sends a data flow by switching data packets. TCP plays an important role in delivering the data to the address without going missing nor permutation of packets. The sender controls the data amount and the router controls data routing.

The topological structure of the internet has been intensively studied and its small world property (Watts and Strogatz, 1998) is revealed. One property that a network has is a hub connection, and this is now widely known in generic information about transporting systems, e.g. gene networks or neural networks in the brain. A.L. Barabasi reported that such small world networks become even more robust when compared with random networks (Barabasi and Albert, 1999).

But we also think it is important to understand the flow dynamics on the internet rather than just its topological structure. Graham proposes PSNs as a new model for a brain system in place of a circuit switching network (Graham and Rockmore, 2011). Griffith et al. argue the similarity between Google’s PageRank system and how the mind works (Griffiths et al., 2007). These are the dynamic properties of a network and we hope that the minimal and prerequisite fundamental dynamics for a kind of intelligence and mind can be found in PSNs.

Indeed, the complexity of the internet’s dynamics has an equally curious property which we find in the human neural circuit. There have been several studies concerning dynamic complexity of PSN (see e.g. (Frommer et al., 2009)). The inherent complexity of PSNs can be seen at the level of producing consciousness-like macro phenomena, which Tononi and Edelman hypothesised with their concept of dynamic core and reentry (Edelman and Tononi, 2000).

We list characteristics in the Table 1 to compare PSNs with the other complex enough network systems. Neural synchronisation phenomena were discovered by Singer in the visual cortex of a cat (Singer and Gray, 1995). Such synchrony is also found as a self-moving pattern in Hippocampus slices (Takahashi et al., 2010) or in the massive number of artificial neural networks (ANN) (Izhikevich, 2000; Izhikevich and Edelman, 2008; Izhikevich, 2006). Here we only refer to the Izhikevich neural net, as this network is realistic in its scale and types of neural spiking. It should be noted that synchronisation is not always a global phenomenon but it is often observed as a local synchronisation or clustering of neural oscillation. In other words, different neural clustering in space and time can coexist. This is a universal phenomenon in generic coupled nonlinear systems (Kaneko, 1990).

What is more interesting is that a localized pattern can propel itself through space; we call these gliders and space-ships in the game of life. A glider or spaceshp is used to prove the universal computability of the game of life as demonstrated by William Poundstone (Poundstone, 1984). Indeed the role of a glider pattern is for a basic information packet to run through the system, and gliders sponta-

Figure 1: An example network has three nodes and one router. Nodes A and B send packets to node C creating two flows.

neously interact with each other to maintain the system’s autonomous information processing. One of the purposes of this paper is to look for similar phenomena in PSNs by taking packets as the simplest form of glider. This notion of autonomy is what we are going to seek in PSNs.

If a system is autonomous and sufficiently complex, we expect it to show various signs of intelligent behavior. One such intelligent behaviour is based on memory dynamics. Therefore, we put memory as the 4th row in the table. Here different kinds of memory are potentially stored in the networks. ANN stores memory as attractors (see e.g. Hopfield network (Hopfield, 1982)), which can be referred to as semantic memory, but it also stores episodic memory as chaotic itinerant dynamics of pseudo attractors (Nozawa, 1992; Tsuda, 2001; Tani, 1998). As discussed at the beginning of this section, the internet now mainly consists of two memory structures. One is Google’s Database (DB) and the other is Twitter’s time line (TL). We think these are related to semantic and episodic memory in real brain systems, except that they are about the application layer. However this is beyond the scope of this paper and will be reported in ASSC 15<sup>2</sup>.

Finally, the game of life stores memory in terms of special spatial configuration. The best known example of a cellular automaton’s (CA) memory might well be von Neumann’s self-reproducing automata (Neumann, 1967). Since the game of life can emulate any kinds of CA, we propose here that any powerful CA can become a universal Turing machine in the game of life.

## The Packet Switching Network Model

NS-2 is a simulator for a packet switching network (PSN). We claim that this network corresponds to the neural network of a brain system, where each connected neuron sends electric pulses to the others with different timing and strengths. At the end of this section we compare the basic properties of PSNs and neural networks, but first we explain how NS-2 works.

To illustrate how NS-2 works, let us consider a simple network where three nodes are connected through one router as depicted in Fig. 1. For example, when node A tries to

<sup>2</sup>ASSC 15 : The 15th annual meeting of the ASSC. <http://www.theassc.org/conferences/assc-15>

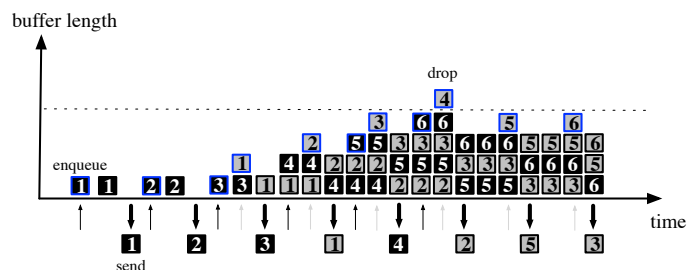

Figure 2: Changes occur in the buffer as the router receives and sends packets with the buffer size equal to four.

send a packet to node C, it goes through the router. The router has a certain length of packet buffer, say four. The packet will be sent to node C if the packet buffer is not over capacity. If the packet is over capacity, congestion occurs and the packet will simply be dropped. Fig. 2 shows the changes in the router’s buffer status when packets 1, 2, 3, 4, 5, and 6 from node A and B are sent to node C respectively. The figure shows the router’s buffer when two flows occur, one from node A to node C and the other from node B to C. The black arrow shows the arrival of the packet to the node, enqueueing the packet to the buffer, then sending the resulting dequeueing of the packet. These two events would show in the logged file of NS-2 as follows:

```
+ time A C 1 1
- time A C 1 1
```

where each line denotes ‘event’, ‘time’, ‘destination node id’, ‘arrival node id’, ‘flow id’ and ‘packet id’. The ‘+’ denotes the enqueueing event to the buffer and the ‘-’ denotes the dequeueing event to the buffer. Similarly, when the node arrives at either a route or a node, it will be logged in the file as:

```
r time A C 1 1
```

where ‘r’ denotes an arrival event. When the buffer becomes full and create a congestion, a dropping event occurs as shown in the figure for node B packet and it would be logged in the file as follows:

```
d time B C 2 4
```

When a drop event happens, that packet will always be lost. The Transmission Control Protocol (or TCP) is a mechanism designed to create more reliable transmissions. TCP sends a packet with a serial number. When a node receives a packet, it sends back the serial number which is called acknowledgement (or ACK). When the sender receives an ACK, then it sends the next packet. If the sender node does not receive an ACK for a certain period of time or receives ACKs with wrong sequence number, then it resends the same packet. However, as one can easily imagine, sending packets one by one is not efficient. To cope with this, TCP has a parameter called congestion window size which

Figure 3: Network topology for the experiment.

defines how many packets the sender can send at one time. This window size is advertised by the receiver node. To improve performance, the advertised window size needs to be set to 'large'. However, when the window size is too large, it creates congestion with other packets resulting in packet drops and consequent requests to re-send the packets.

While the advertised window size is imposed by the receiver, there is another window size imposed by the sender called the congestion window size, or called the "cwnd". When a new connection is established with a node, the cwnd is initialized to one segment (i.e. the segment size is announced at the other end). Each time an ACK is received, the cwnd is increased by one segment. The question about how to improve performance then becomes how to adjust the advertised window size and the cwnd size. The former is related to the amount of available buffer space at the receiver for the connection; the latter is based on the sender's assessment of perceived network congestion. It is important to note that the cwnd size continues to increase to a given threshold or until a drop event happens.

There are a number of different algorithms to increase the cwnd size. The one we used in this study is called Reno. The Reno algorithm increases the cwnd exponentially until the first packet drop occurs due to congestion. After the first drop, the cwnd is set to half then continues to update itself in a linear manner. When a drop happens, it again sets to half and starts to increase again and continues this process throughout.

As we have explained so far, PSNs (and the simulator, NS-2) have the following corresponding properties when compared to biological neural networks:

- Flow dynamics in PSNs correspond to the pulse trains of neural activities.
- A buffer size corresponds to the activation threshold of a neural firing. In the NS-2 model we use 10 as the buffer size and the threshold of a real neural cell is about 15 mV.
- Strength of the cwnd corresponds to synaptic strength. Here we have Reno algorithm to change the window size.
- A drop event corresponds to the fact that neural pulses cannot contribute to an overshooting event.

Having this correspondence in mind, we analyse and explore the PSN in the next section.

## Analysis

We have conducted experiments using NS-2 on a simple network topology with a 30 node setting where each node is

Figure 4: An example of spatio-temporal packet flow pattern. The horizontal axis is time (each step is 10 msec) and the vertical axis is the spatial node (here the total number of nodes is 30). As this figure shows, each packet flow spontaneously bifurcates so that lines are multiplied. Every flow shows concatenated "V-shaped" pattern, since every successfully received packet is followed by ACK signal sent back to the sender.

connected to the next node as depicted in Fig. 3. The analysis will be on the flow dynamics, the congestion phenomena and the robustness of the flow patterns when pouring a temporary flow from outside. We will explain these below.

## Flow dynamics

A unique characteristic of a PSN is a self-tuning cwnd size for each flow in the network. In the first simulation, we created 30 flows in which each router sends a series of packet data to its neighbors through an optimised routing pathway (or trace). All flows are set to have an equal length. As described above, each packet between connected nodes ( $i \rightarrow j$ ) is characterised by a triplet (+,-,r) state, where the state "+" corresponds to "the packet in node  $i$  is ready to send", "-" to "the packet has been sent to node  $j$ " and "r" to "the packet has been received by node  $j$ ". Using this information, we can visualise the spatio-temporal flow pattern as shown in Fig. 4.

As for basic observations, we see i) The more numbers of nodes the flow travels, the more transport time is required; ii) Due to spontaneous time delays, packets that constitute the same flow arrive in different timeframes, which causes the bifurcation of flow pathways. This bifurcation pattern can be different for each flow; iii) Even within the same flow and in between the same traces, the bifurcation pattern can vary temporarily.

It should be noted that the bifurcation of flow path due to the time delay in point (ii) above is a novel feature in dy-

Figure 5: The number of drop events as a function of the integrated input packets (we call a 'duty ratio') on each source node. Input packets are given periodically for each node. When duty ratio =  $x (< 1)$ , it means that each source node sends packets for  $x$  seconds and rests for the next  $(1 - x)$  second for every cycle.

dynamic systems. In PSNs, flow is spontaneously quantized into a series of packets when transporting to other nodes. This clustering event is not written in the form of an "equation" in the PSN but happens only as a result of congestion and timing. Although such spontaneous clustering is similar to congestion patterns studied in traffic models (Chowdhury et al., 2004), PSNs have drop events and ACK signals. In the case of traffic jams, vehicles or ants will never disappear. This traffic jam phenomenon is called congestion. Bifurcation of flow pattern is correlated with this congestion pattern, which we will focus on in the next section.

### Congestion Flow

As explained in the previous section, the source node of each flow tunes the buffer size and the cwnd size to reduce the drop events. When the amount of flow becomes larger than a specified volume, congestion occurs spontaneously and the number of drop events increases exponentially as the amount of flow increases. Fig. 5 shows an increase in the number of drops as the ratio of the packet flow period to the frame increases.

The drop events trigger the clustering of the window size. In the first hundreds steps, each window size is mutually tuned and their phases are synchronised as shown in Fig. 6. This is known as TCP global synchronisation<sup>3</sup>. In the figure, all flows are set to have an equal length. In this case, even though the cwnd size changes from a periodic to an aperiodic state the packet flow is mostly periodic. Because

<sup>3</sup>TCP Global Synchronisation : [http://en.wikipedia.org/wiki/TCP\\_global\\_synchronization](http://en.wikipedia.org/wiki/TCP_global_synchronization)

Figure 6: An example of the cwnd dynamics. Each window size of the flow is overlaid multiple times. Here the system has a few drop events so that the network settles down to a periodic synchronized pattern after four seconds.

almost all the drop events occur at the source of the flow, the drop events change the cwnd dynamics but not the packet flow pattern.

We artificially create a special topology that produces massive congestion in the middle nodes (i.e. between nodes 14 and 15 of the 30 nodes). In this case, both the flow patterns and the cwnd dynamics become unstable, as the drop events occur not only at the source but also at the relay nodes. Some examples of the flow patterns and cwnd patterns are depicted in Fig. 8. The transport time of every flow shows a power law behavior of the exponent being equal to -2 as shown in Fig. 7. The connection between nodes 14 and 15 becomes a bottleneck and determines the entire time scale.

When a cwnd dynamic settles into a periodic state, its periodicity becomes almost consistent with its varying window size. In the case of aperiodic cwnd dynamics shown in Fig. 8, we classified this into five clusters based on the temporal oscillating pattern as we do for the dynamical systems.

1. Periodic state: The window size changes periodically in a stepped way. Fig. 8-(a) represents this cluster.
2. Chaotic state: The window size changes in an aperiodic way. In the case of Fig. 8-(b,c), we have two different chaotic behaviours; one with fast amplitudes varying in time and one with slow amplitudes changes in time, where their time scales also show some variations.
3. Intermittent chaotic state: The periodic oscillation of window size is intermittently perturbed by a burst of large window size. The other intermittent behaviour is that the amplitude almost periodically oscillates around a certain

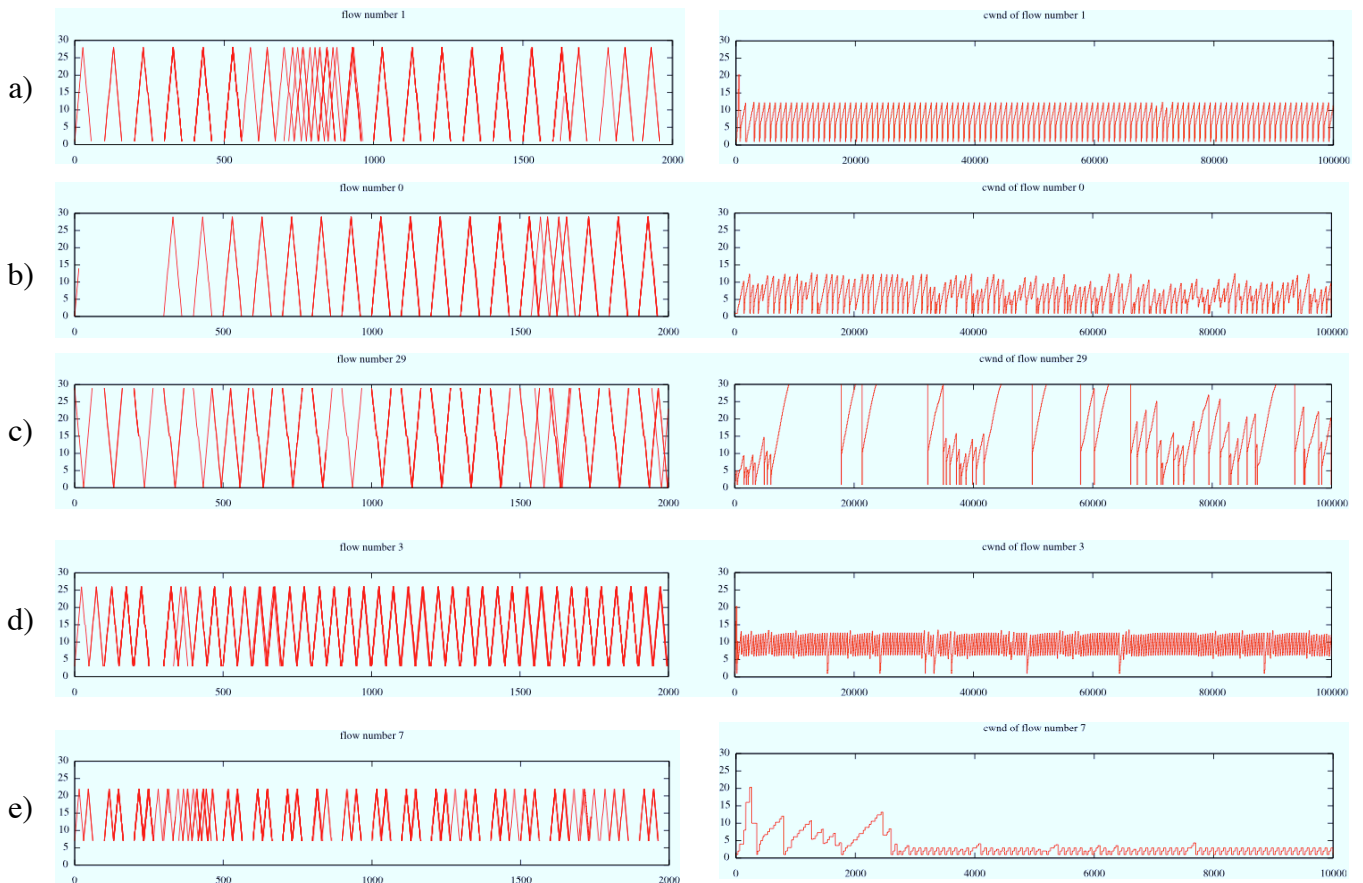

Figure 8: Examples of five categories of cwnd dynamics (right) and the corresponding packet flow pattern (left). From the above, these are: a) periodic, b) chaotic type 1, c) chaotic type 2, d) intermittent chaos type 1, and e) intermittent chaos type 2. Time scale is set from 0 to 100,000 except for the case e), since the oscillation of case e) is much faster compared to other cases. See the details in the text.

value but is intermittently perturbed by a larger or smaller (often null) window size. Both of these can be observed in Fig. 8-(d,e).

Flows synchronised in the same clustering pattern can be found in the spatial neighbors with some exceptions. It should be noted that the chaotic synchrony is what we compare with the Hippocampus slice or Izhikevich neural ensemble as a candidate for the origin of autonomy and a computation primitive. As discussed in §2, these synchronised patterns are important in maintaining the functionality of the network as a whole. In particular, we propose that these synchronised patterns may be a source of PSN autonomy.

### Perturbation

Let us perturb the flow network by pouring an extra flow from outside at a certain time duration. A stable network, where both flow and cwnd pattern become periodic, will remain robust against the perturbation, i.e. the flow pattern and cwnd dynamics will remain periodic. On the other hand, a

network that has massive congestion at the middle point is less robust against perturbation. Comparisons before and after perturbation demonstrate that flow pattern (Fig. 9) and cwnd dynamics will be different. In other words, the flow state can be said to have chaotic instability as it amplifies the small difference caused by the extra flow input.

It can be said that for this special network, the flow state becomes less robust against perturbation. But we also interpret the state as adaptive because it never falls to a fixed flow state.

### Discussion

The autonomy we are looking for is having the flexible internal dynamics to change responses against external inputs. A certain amount of chaotic dynamics may be responsible for this. In previous studies, we have partially proven that an autonomous robot equipped with the coupled FitzHugh-Nagumo equations shows such autonomy (Aucouturier et al., 2008). Analysis of how such a robot can

Figure 7: Distribution of throughput time duration. The distribution of the shorter time duration shows the power law behavior, which corresponds to the bottleneck connection between the 14th and 15th nodes.

interact with the environment was the focal point.

In the present paper, we have studied PSNs to reveal the internal flow dynamics and the system responses to external pulse inputs. When increasing the amount of flow from the outside, we showed that cwnd dynamics change from periodic to chaotic. In the case of a network with a bottleneck edge, the transport time of each flow obeys the power law and the real packet flow becomes chaotic for a long period of time.

In §1, we posed a question, "what happens if everybody stops accessing the internet?". An answer to this question might be "it won't stop immediately but will last a long time because it does not attain a stable pattern as shown from the PSN experiment". The ever-changing nature of chaotic and intermittent clustering may drive the autonomy of the internet even with periodic inputs supplied, for example, by automated web crawlers. If a simple one-dimensional PSN can have complex clustering patterns, the internet with its massive data flow should have ever-lasting and changing clustering, thus making it autonomous. We believe these findings correspond to the examples of complex networks in Table 1. That is, autonomous networks can develop complex local/global space time clustering or gliders.

We also claim that PSNs are a novel class of dynamic systems that spontaneously bifurcate their flow structure and may be the backbone of the internet today. The corresponding gliders in the game of life and other intelligent systems in Table 1 remain stable. However in the case of PSNs, those localised patterns can bifurcate. This bifurcation of glider-like patterns is why we think this PSN is a new interesting testbed for Artificial Life studies. As for future investigations, we have to pay more attention to other novel features

Figure 9: Comparison of space time plots of drop events for the original and the perturbed network (the horizontal axis denotes the network node IDs and the vertical axis denotes time steps). The perturbation is introduced as a pulse packet flow of duty ratio=1 poured during 10,000 and 20,000 msec-onds. After the perturbation, a network does not come back to the original state.

of PSNs. For example, dynamic routing and another TCP/IP will be a future research target.

Our analysis here is about the transport layer not the application layer. Examples of autonomous software in the application layer include web crawlers, peer-to-peer software, and SNS bots. The existence of those two layers does contribute to making a more complex autonomous system. Within a computer system, an example of a software algorithm that generates chaotic dynamics in the hardware layer was reported by Berry et al. in 2006 (Berry et al., 2006). We are now studying the autonomous behavior in the application layer using the notion of clustering dynamics found in the PSN reported in this paper.

# Simulation of cell-like self-replication phenomenon in a two-dimensional hybrid cellular automata model

Takeshi Ishida<sup>1</sup>

<sup>1</sup> Nippon Institute of Technology  
ishida06@ecoinfo.jp

## Abstract

An understanding of the generalized mechanism of self-reproduction is fundamental to applications in various fields, such as the mass-production of molecular machines in nanotechnology. We have developed a model for the simulation of cellular self-reproduction in a two-dimensional cellular automaton, and we have demonstrated that the following three functions can be realized: (1) formation of a border similar to a cell membrane, (2) self-replication while maintaining carrier-containing information, and (3) division of the cell membrane while maintaining the total structure. Furthermore, we have constructed a hybrid cellular automaton model. To reduce the number of transition rules, we considered not only the state transition rules but also the concentration diffusion in the Gray Scott model, in which the self-reproduction phenomenon emerges under certain parameters.

## Introduction

An understanding of the generalized mechanism of self-reproduction is considered fundamental to applications in various fields, such as the mass-production of molecular machines in nanotechnology and artificial synthetics in biology (synthetic biology). Furthermore, it is difficult to construct large, complex machine systems that exceed a certain size, using a top-down approach. Therefore, such complex systems must be constructed using a bottom-up approach based on the phenomenon of biological self-organization. Thus, it is crucial to elucidate not only the details of real cellular reaction networks but also the conditions necessary for self-organized and self-replicating cells.

A system that can simulate the self-reproduction of a cell must fulfill the following requirements. 1) It can express phenomena of nanolevel molecular behavior such as the Brownian movement. 2) It can express a chemical reaction system. 3) It can express the shape (difference in reaction process according to the shape) of compounds such as proteins. 4) It can express the emergence of macro shape and function for a bottom-up approach. For such a calculation, a particle system model is a potentially superior option.

Fifty years ago, von Neumann (1966) initiated a study on self-reproduction models from a mathematical viewpoint. His study theoretically proved the possibility of constructing a self-reproducing machine using cell states and the transition rules of two-dimensional square cells. However, von Neumann's

self-reproducing machine was large; therefore, it is difficult to implement this machine perfectly in a computer system (Mange, 2004). In 2010, Hutton (2010) implemented and simulated over its entire replication cycles. Later, Langton (1989) developed a simple machine capable of self-reproduction, by abandoning the completeness of von Neumann's machine; although its shape was quite simple and it could reproduce specific shapes, the rules of transition were complicated. The derivation of transition rules using genetic algorithms has been investigated (Reggia, 1998)(Sipper, 1998); however, it is difficult to derive the generalized rules.

Historically, researchers have attempted to develop a mathematical model to simulate the morphosis of living matter. Studies on the reproductive models of a body surface design, namely, the Turing model (Turing, 1952), and those on the leaf vein pattern of a plant (Feugier, 2005) and mollusk shell patterns (Meinhardt, 2003) are examples of previous research. In addition, many researchers have used a cellular automaton model to study tissue or tumor growth. Although these models can simulate a number of features of biological self-reproduction on a computer, they cannot reproduce the entire body on the basis of unified equations and rules, such as cytodifferentiation by gene expression→morphosis of cells→organogenesis→emergence of function.

In our previous study (Ishida, 2010) we developed a model for the simulation of cellular self-reproduction in a two-dimensional cellular automaton. We demonstrated that the following three functions could be realized by the transition between two adjacent cells.

- (1) Formation of a border similar to a cell membrane.
- (2) Self-replication while maintaining carrier-containing information (information carrier).
- (3) Division of the cell membrane while maintaining the total structure of the cell.

In this study, we demonstrate the self-reproducing ability of a shape that is similar to that of a real living cell. Figure 1 shows the results of a cell-type self-reproducing two-dimensional cellular automaton. It is important to note that the objective of this study is not to clarify all the necessary and sufficient conditions for self-reproduction. Instead, we consider the possibility of simulating self-replication in a real dynamic chemical reaction environment by applying the transition rules determined in this study. A similar previous studies by Ono, Ikegami (2000), and Hutton (2007). Ono & Ikegami does not completely lead to the replication of the

same cell. Hutton's work involves self-reproduction that does not include information carriers such as genes. The latter point indicates the novelty of the present study.

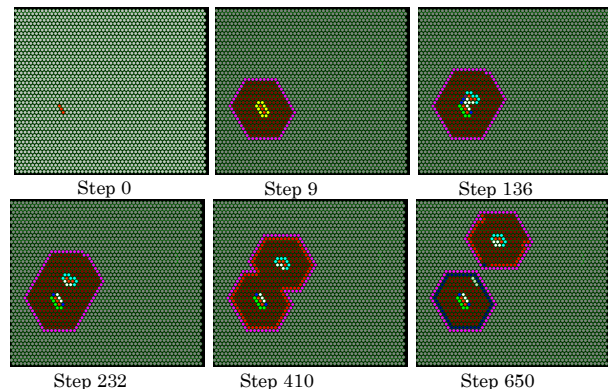

Figure 1 Results of a cell-type self-reproducing two-dimensional cellular automaton (Ishida, 2010)

## Objective

In this study, we constructed a hybrid cellular automaton (CA) model. Figure 2 shows the outline of the hybrid model. To reduce the number of transition rules, we considered not only the state transition rules but also the concentration diffusion of the field. We chose the Gray Scott model (GS model) (Gray, 1984), in which the self-reproduction phenomenon emerges with certain parameters. In this hybrid model, information carriers trigger the self-reproduction phenomenon of the GS model, and a cell membrane is formed by a part of the specific concentration of the GS model. If a single cell is being simulated, cell membrane formation is possible using a linear diffusion equation. This is difficult to accomplish using a simple linear model, and the GS model is necessary to fill the space while multiple cells are adjacent to one another and to maintain the distance between them.

This model is new, and it can be combined with existing models, such as the reaction diffusion equation models in the CA model. We express a macromolecule system in the CA model, and we express the small molecule-based reaction system that constitutes a reaction diffusion model, because the calculations become enormous when we calculate the reactions of all the molecules.

The simulation of a real living cell was considered difficult to express with only two phases, but it was based on future development. Furthermore, because a simple chemical reaction system can be substituted for the GS model, it is thought that we can simplify the model in the future.

As shown in Figure 3, we arranged the transition rules in the CA model and the GS equation parameters in two-dimensional space in order to simulate the duplication of hereditary information carriers, the encapsulation of information carriers by a cell membrane, and maintenance of the shape of the membrane.

Cellular automata possess characteristics that can help us understand the association between transition rules and results so that a state is determined solely by the rules governing the

transition between adjacent cells. In addition, the cellular automaton model has already been applied to discrete particle simulation, as in the case of fluids. For these reasons, it is theoretically possible to apply the transition rules to chemical or particle-collision systems.

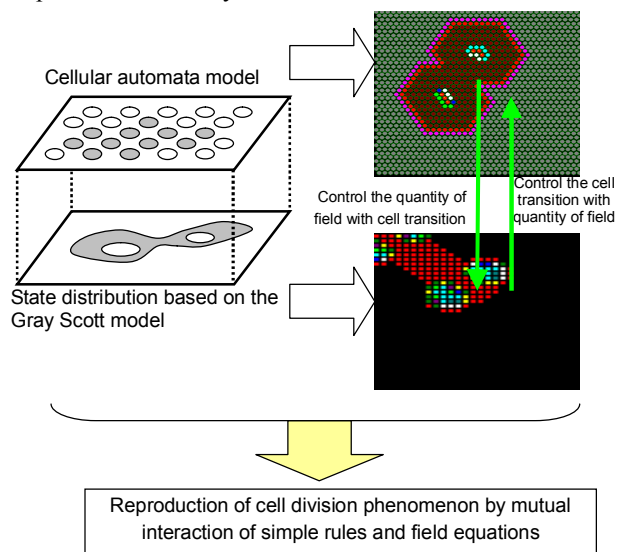

Figure 2 Outline of hybrid cellular automaton model

Figure 3 Conceptual diagram of cell-type self-reproduction in two-dimensional cellular automata

## Research Method

### Cellular automaton model

A two-dimensional hexagonal grid model was used in this study (Figure 4). Although square grids are typically used for two-dimensional cellular automata, a hexagonal grid model was used in this study for two reasons.

- (1) In the case of a square grid, the state of an automaton in the next step is determined on the basis of the state of the cell itself and the states of the eight adjacent sites. This increases the number of transition rules, and consequently their complexity. In the case of a hexagonal grid, the state of the next step is determined by the state of the cell itself and the states of the six adjacent sites. This reduces the number of transition rules.
- (2) Isotropy in the horizontal/vertical and diagonal directions is maintained in a hexagonal grid but not in a square grid.

The cell automaton was constructed according to the transition rules so that the state of the next step was determined by the state of the cell itself and the states of the six neighboring cells. Each cell had a state (0–19 states) and a direction (6 directions) as attributes.

0: State of non-being

1: States in which hereditary information carriers (Only states 1 and 2) have a directional attribute (any one of the 6 directions)). We can describe various types of information by creating subspecies (1-a, 1-b, etc.) for state 1.

2–10: States in which the nuclear membrane surrounds the hereditary information carriers

11–18: States that constitute space within the cell

19: States that consist of the cell membrane

In a hexagonal grid, the calculations start from a certain initial condition. As shown in Figure 5, the transition rules were divided into the following 4 phases: 1) state transition as regards cell membrane formation, 2) division of the information carriers, 3) movement of the information carriers, and 4) formation of a nuclear membrane surrounding the information carriers. In other words, we first applied the transition rules for cell membrane formation and settled the total states in all cells. Then, we applied the transition rules for the division of information carriers, after which we applied the transition rules for movement of the information carriers and formation of the nuclear membrane.

To induce objective state transitions of the cellular automata, we added transition rules to remove the unnecessary side effect reaction at the same time. We divided the

Figure 4 Hexagonal grid model used in this study

transitions into 4 phases to discover the transition rules, because discovery of the entire set of transition rules was difficult to achieve all at once.

### Gray Scott (GS) model

The cell transition patterns in this cellular automaton model resemble those of physical phenomena. Thus, we considered the possibility of replacing the transition rules with those of a non-linear quantity model such as the GS model. The equations for the GS model are given below. The self-replication patterns occur under certain conditions ( $D_u = 0.04$ ,  $D_v = 0.02$ ,  $F = 0.02$ , and  $k = 0.06$  in this study).

The initial concentrations of  $U$  and  $V$  assumed for the differential equation of the GS model were 1.0 and 0.0, respectively. This is a steady state in which there is no change in the concentration distribution. When there is a change in the concentration level in some spatial position, this triggers a dynamic change. When state 19 exists, the concentration distribution in the GS model in the same spatial position changes (from  $U = 1.0$  and  $V = 0.0$ , to  $U = 0.25$  and  $V = 0.35$ ). This unstable state leads to changes in the concentration distribution of the GS model.

On the other hand, as regards the action from the GS model to CA model, it is as follows. We calculated the ratio  $(500-U)/V$  of density  $U, V$  in the GS model and divided it into 10 parts between the minimums and the maximum of the value, and thus derived a potential level (1-10). A transition was induced in the CA model space when the condition appeared of a potential level shown in Table 4 on the GS model.

In addition, in the GS model, we can clarify the parameter set for when a self-reproduction design appears, but we cannot control the size of the self-reproduction design. Therefore, we adjusted the space scale of the CA model and the space scale of the GS model so that a cell membrane that encapsulated an information carrier was formed. The theoretical determination of the space scale method requires further investigation examination.

$$\frac{\partial V}{\partial t} = D_v \Delta V - U^2 V + F(1 - V) \quad (1)$$

$$\frac{\partial U}{\partial t} = D_u \Delta U + U^2 V - (F + k)U \quad (2)$$

### Transition rules

Each cell was renewed by the transition rules, and the state of the next step was determined by the state of the cell and the states of its 6 neighboring sites. The transition rules are presented in Tables 1–4. We have not yet discovered a method with which to derive transition rules automatically according to a uniform law. Therefore, we constructed transition rules step-by-step according to the movements of the automaton.

In this hybrid model, the information carriers first activate the GS model. Cell membrane states appear under certain concentrations of the GS fields. The movement of the nuclear membrane was controlled by the concentration of the GS fields.

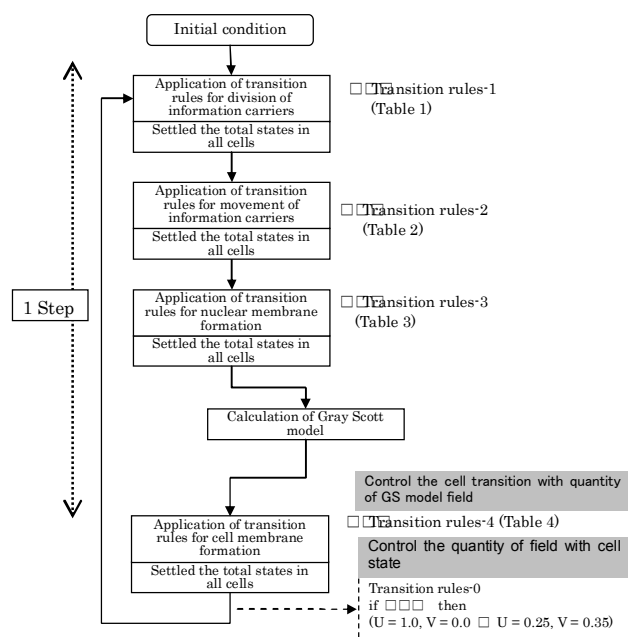

Figure 5 Calculation flow

## Initial conditions

Figure 6 shows the initial condition. The entire cell is in state 19. State 1 indicates the information carriers, three of which are arranged consecutively in the central part. The

intersection of state 19 and state 1 triggers the GS calculation. The purpose of this study is to find a minimum set of transition rules to achieve self-reproduction in a two-dimensional cellular automaton space. Our transition rule does not realize self-reproduction in any initial state.

## Results

Figure 7 shows the process of cell membrane formation and the process of the division of information carriers within the cell membrane. We carried out calculations for 101 steps; some of our results are shown in the figure. In each image in the figure, the upper part is the CA model and the lower part is the distribution of the potential level by the GS model. In this way, we were able to replicate the phenomenon of cell-like division.

Table 5 shows the number of transition rules for the cellular automaton model (Ishida, 2010) and the hybrid model. Using the hybrid model, we reduced the number of transition rules. In the case of the CA model, the transition rules to synchronize the cell-centered nuclear shape and the shape of the cell membrane were complicated. In the hybrid model, on the other hand, self-replication was possible with fewer rules, such that a cell membrane was formed on areas of a specific concentration. As compared with the CA model, the hybrid model is complicated in terms the calculation of the GS model; however, simpler rule description will be possible in the future because the GS model can replace the simple metabolism system.

## Conclusion

In this study, we constructed a model of a hybrid cellular automaton model. Our model displayed self-reproduction in a cell-like shape with few state transition rules. To reduce the number of transition rules, we considered not only the state transition rules but also the concentration diffusion in the Gray Scott model, in which the self-reproduction phenomenon emerges with certain parameters.

The future direction for this research includes the discovery of other sets of transition rules, identification of a way to derive transition rules automatically on the basis of a uniform law, and theoretical application of transition rules to particle collision.

Figure 8 shows the overall perspective of our artificial cell simulation. We believe that the transition rules of this model can be applied to the simulation of self-replication phenomena in a real dynamic chemical reaction environment. Initially, we plan to simulate cell division in a discrete particle reaction. It is relatively easy to replace state transition rules with collision/reaction rules of discrete particles. Next, we plan to simulate cell division in a continuous chemical reaction by converting discrete particles rules into chemical equations.

# Social Learning and Evolution in a Structured Environment

Daniel Jones<sup>1</sup> and Tim Blackwell<sup>1</sup>

<sup>1</sup>Department of Computing, Goldsmiths, University of London, UK  
d.jones@gold.ac.uk, t.blackwell@gold.ac.uk

## Abstract

We survey the relationships between evolution, individual learning and social transmission within well-mixed and structured environments. With a novel individual-based simulation, we determine the regimes under which each mode of learning dominates, in terms of the environment's relative complexity and its rate of change. We show that social learning can give rise to a particularly potent form of the "Baldwin effect", wherein an organism develops an innate trait having first acquired it socially. We demonstrate that social learning is of increased significance in a structured environment.

## Introduction

To operate successfully in a Darwinian system, it is advantageous to possess maximal information about our environment. This is reflected in the functional information that all living creatures inherit via DNA, which codes for the set of functional characteristics most likely to benefit an organism in its future surroundings (Avery, 2003).

However, the environment which produced a parent is never quite the same as when its child is born. Ecological habitats are continually changing as their inhabitants consume and produce resources, with environments effectively co-evolving with their organisms. Inheritance is thus an intrinsically probabilistic process, which uses rules of thumb to provide the best possible solution given the expected habitat based on previous generations (Seth, 2007).

To optimally deal with uncertainty, all organisms exhibit some degree of *phenotypic plasticity* (West-Eberhard, 1989; Scheiner, 1993): the ability to alter behaviour or physiology in response to environmental conditions. By allowing some morphological decisions to be fixed later in an organism's lifetime, evolution can effectively defer decisions about functional specifics. This appears to be particularly prominent in fluctuating and heterogeneous environments, which are naturally less predictable (West-Eberhard, 1989).

## Evolution, learning and culture

The most radical form of phenotypic plasticity is behavioural learning, which can respond rapidly and flexibly

to novel stimuli based on prior experience. Learning can be considered as giving foresight to the blind process of evolution, by enabling an organism to search the fitness landscape around the point determined by its genotype (Belew, 1990; Borenstein et al., 2006). As Maynard Smith (1987) observes,

"...finding the optimal [solution] in the absence of learning is like searching for a needle in a haystack. With learning, it is like searching for the needle when someone tells you when you are getting close." (Maynard Smith, 1987, p762).

In this paper, we are concerned with two forms of learning: *individual exploration*, which we shall define as trial-and-error learning solely between an individual and its (abiotic) environment; and *social learning*, in which an organism acquires traits by observing or mimicking the behaviours of others (Lefebvre and Palameta, 1988). Countless species engage in social learning (Galef and Laland, 2005; Laland, 2004a), through mechanisms such as mimicry, teaching, and goal emulation. We shall here deal with a general case in which a trait is exhibited after observing another organism as a model (the "exemplar").

When evolutionary systems are extended with lifetime behavioural plasticity, we should expect some interesting interactions to arise. One which came to the attention of the first generation of evolutionary theorists after Darwin (Baldwin, 1896; Morgan, 1896) is the "Baldwin effect", a term coined half a century later (Simpson, 1953) after one of its progenitors, ironically in an attempt to discredit the theory.

The general pattern encapsulated within the Baldwin effect is as follows:

1. A population arises in which some trait  $P$  becomes beneficial.
2. Some individuals arise which, through their phenotypic plasticity, are able to learn  $P$ .
3. In some of these individuals, the trait  $P$  becomes innate (*genetic assimilation*).

With the assumption that innate behaviours are less costly than those which are plastic, we would then expect selective pressure to lessen on these particular learning capabilities: if we can do it by nature, we no longer need to be able to learn it (West-Eberhard, 2003).

The status and prevalence of genetic assimilation within real-world ecosystems is as yet unresolved, and subject to some controversy (Pigliucci et al., 2006). Due to its onerous requirements – a species sufficiently advanced to partake in social learning, bred over a sufficient number of generations for a trait to become genetically incorporated – it is difficult to observe via *in vivo* studies, though Waddington’s (1953) “veinless” study elegantly demonstrates its biological plausibility. It is, therefore, a well-suited candidate for *in silico* experiments.

### Theoretical studies of social learning

A large body of theoretical work has been developed at the confluence between evolution, learning and cultural transmission (Cavalli-Sforza and Feldman, 1981; Boyd and Richerson, 1985; Wakano et al., 2004). The watershed work was a computational model by Hinton and Nowlan (1987, henceforth ‘H&N’), who extended binary genetic algorithms with an undefined third value, whose outcome is determined by lifetime learning. Though intentionally simplistic, this model effectively demonstrated the “needle in a haystack” function of learning as a dowsing rod to guide evolution towards discontinuous fitness peaks.

Belew (1990) and Best (1999) have extended H&N with differing forms of cultural transmission, both in a well-mixed environment, incorporating oblique and horizontal forms of social exchange. While Belew models cultural exchange as a bias towards higher fitness, we will follow Best as treating it as a more neutral form of behavioural mimicry, in which an organism may imitate deleterious as well as adaptive behaviours.

Models of social transmission within a spatial environment include work by Boyd and Richerson (1988), Lowen (1996) and Borenstein (2003). A consensus view has emerged that sociality is of benefit within structured environments. We wish to extend these analyses to survey the regimes under which each mode of learning excels, and whether unforeseen mixed strategies may come to the fore given a heterogeneous, individual-based model.

We also wish to model the scenario conjectured by Papineau (2005), who posits that the Baldwin effect may become significantly more prominent when bolstered with social learning. This can be roughly encapsulated by the inequality:

$$p(G) \ll p(L) \ll p(S) \quad (1)$$

Where  $p(G)$  is the probability of exhibiting a trait innately,  $p(L)$  is the probability of learning it through ex-

ploration, and  $p(S)$  is the probability of acquiring the trait through social learning. Quite simply, wherein it is effectively impossible to acquire a functional trait  $P$  through evolution – perhaps because it is comprised of multiple sub-traits, which are jointly necessary to reap a fitness benefit – this process may be somewhat more likely when lifetime learning is possible, and even moreso when social learning enables organisms to share traits.

This argument, though intuitively sound, is thus far based on heuristic assumptions. The following model is intended to quantitatively explore situations in which a social Baldwin effect can take place, and particularly those in which combination strategies can arise: evolved individuals can exhibit both individual and social learning in proportion. We are furthermore interested in how these phenomena interact in a context which is explicitly spatial, a combination which has not yet received significant attention.

### Model specification

We will now describe the components of the individual-based model used to explore these ideas<sup>1</sup>. An *environment*  $E$  consists of a  $B$ -bit string, representing a ‘target’ task:  $E \in \{0, 1\}^B$ . The current environmental state can therefore be considered as a vertex on an  $B$ -dimensional hypercube.

It is inhabited by a population of  $N$  agents, each of which has the following properties:

- $b_{evo}, b_{exp}, b_{soc} \in [0, 1]$  – *behavioural traits* determining the propensity towards evolutionary instinct, individual exploration, and social learning. These are collectively normalised to sum to unity.
- $g \in \{0, 1\}^B$  – *genotype*, a  $B$ -bit string corresponding to the capability to fulfil the environment’s target task.
- $p \in \{0, 1\}^B$  – *phenotype*, a  $B$ -bit string initially equal to  $g$ , but subject to modification through individual and social learning. If  $p$  is equal to  $E$  then the agent’s fitness is maximised.
- $\Omega$  – current metabolic state, initialised to a constant  $\Omega_0$ .

An agent’s current phenotype determines how well it complies with the environment’s demands, based on its Hamming distance from  $E$ . Its metabolic state determines the extent to which it has ‘grown’ throughout its lifetime.

### Actions and learning

Every timestep, each agent selects a behavioural mode according to a weighted random of  $\{b_{evo}, b_{exp}, b_{soc}\}$ :

- $b_{evo}$  – act according to the agent’s current phenotype
- $b_{exp}$  – act according to the agent’s current phenotype, with  $\beta$  bits toggled at random

<sup>1</sup>For all subsequent parameter values, see the *Methods* section.

- $b_{soc}$  – act according to the agent’s current phenotype, with  $\beta$  bits copied from a neighbour using roulette wheel selection weighted by  $\Omega$ . With a probability  $p_{noise}$ , each of these bits may be copied erroneously (that is, toggled from  $0 \rightarrow 1$  or  $1 \rightarrow 0$ ). This models the inaccuracy present in real-world imitative learning: a behaviour may be only partially observed, or reproduced incorrectly.

If  $b_{exp}$  or  $b_{soc}$  is employed *and* the resultant action gives a higher payoff than the agent’s own current phenotype, the corresponding bits in  $p$  are replaced by the new action: discovering (or imitating) a successful new trait results in its being incorporated into the agent’s roster. This reflects phenotypic plasticity, where  $\beta$  is the limiting factor on the rate at which new skills can be acquired.

In the case of  $b_{soc}$ , weighting the exemplar by their  $\Omega$  value reflects a tendency towards mimicking those organisms which are perceived as being fittest. This is described by Laland (2004b) as a “*copy-successful-individuals*” strategy, as observed in avian, chimpanzee and bat societies.

The agent’s metabolism is then modified according to the following update rule:

$$\Delta\Omega = \left(1 - \frac{H(p, E)}{B}\right)^{\alpha-1} \quad (2)$$

where  $H$  denotes the Hamming distance between two bit strings. The exponential of  $\alpha$  is used to determine the fitness differential between perfect and almost-perfect task fulfilment: a lower value of  $\alpha$  means that payoffs fall more rapidly with distance. With  $\alpha = 1$ , scaling is linear in distance.

In general, if an agent’s  $g$  matches precisely the tasks specified in  $E_i$ , its metabolism will increase by the maximal value of 1. If  $g$  is precisely the complement of  $E_i$ , its metabolism will increase by 0.

Taken as a population mean, the metabolic rate  $\Delta\Omega$  can be considered as a measure of *fitness*, as it is directly proportional to reproductive rate. We will subsequently use the terms interchangeably.

## Reproduction

When an agent’s metabolism  $\Omega$  reaches the value  $2\Omega_0$ , the agent reproduces asexually. Its offspring has an identical genotype, subject to each bit of  $g$  mutating with small probability  $p_{mut}$ . Behavioural traits  $b_{evo}$ ,  $b_{exp}$ ,  $b_{soc}$  are modified by a zero-mean Gaussian noise function, standard deviation  $\mu$ , and clipped to  $[0, 1]$ . These are again collectively normalised to unity. The child replaces a member of the population selected uniformly randomly, and its parent’s  $\Omega$  value is reset to  $\Omega_0$ .

Sexual recombination was considered as a reproductive strategy. Kauffman (1993) observes that recombination is an effective method of finding ‘middle ground’ locations between points on a complex fitness landscape. However,

Figure 1: Distribution of behaviours in a static environment, averaged over 25 simulation outcomes.

given our single-peaked landscape, we focus on clonal reproduction for the sake of simplicity. A number of recombinative trials indicated that the results would not be qualitatively different.

## Results

The results of this model are presented in incremental form, with processes introduced gradually. The motivation behind this approach is to understand pairwise interactions between adaptive mechanisms. By doing so, we hope to fully understand the causal basis behind the emergent phenomena.

### Static environment

We initialise the environment’s task to  $1^B$  for clarity (following Hinton and Nowlan (1987)). Behavioural traits are initialised to uniformly random values, and the population left to evolve.

The changing distribution of behavioural traits over time is shown in Figure 1, as averaged over multiple iterations (see Methods). At step 0, the frequency of each is  $\frac{1}{3}$ , indicating the initial uniformly random distribution of behavioural modes.

The dynamics can subsequently be divided into three phases. (i) Between steps 1–4000, the population is dominated by social learners, with a generally low level of genotypic fitness meaning that a costlier but fitter social learning is preferable. (ii) From steps 4000–9000, the trait has been assimilated into the genotype of the majority, and so innate  $b_{evo}$  agents outcompete their costlier plastic rivals. (iii) Beyond step 9000, a stable optimum is reached.

Sharpening these costs by reducing payoff scaling factor  $\alpha_0$  results in a more rapid convergence to a predominantly  $b_{evo}$  population. This also reduces the effectiveness of lifetime learning, of course, which introduces a penalty in fluctuating environments.

This is a clear example of the Baldwin effect. Phenotypically plastic individuals first outcompete their peers (*i*) as they scramble to higher fitness through learning and social exchange, and are subsequently replaced (*ii*, *iii*) by innate mutants, who do not bear the costs of exploration.

A repeated trial wherein all agents begin with a genotype of  $1^B$  reveals, as anticipated, that they continue to maintain a stable state with only low levels of social and individual learning.

### Static environment with restricted strategies

The above experiment was repeated with a fixed trait mutation factor of  $\mu = 0$  and initial behavioural traits restricted to specific combinations: either pure evolutionary learning ( $b_{evo}$ ), or evolution plus learning ( $b_{evo} + b_{exp}$ ), or evolution plus social learning ( $b_{evo} + b_{soc}$ ), or all three traits in combination.

Figure 2: Convergence rates with four different strategies:  $b_{evo}$ ,  $b_{evo} + b_{exp}$ ,  $b_{evo} + b_{soc}$ , and  $b_{evo} + b_{exp} + b_{soc}$ .

Figure 2 depicts the relative effectiveness of each strategy in a static environment, plotting the global mean fitness (that is,  $\Delta\Omega$ ) over a number of generations. The key indicators of success are the convergence rate and the value to which the population converges.

All four strategies eventually converge around the same peak of 0.8. The times taken to do so, however, are markedly different. Notably, evolution plus learning takes substantially more time to converge than pure evolution alone, and continues to trail throughout the simulation. This confirms the findings of Borenstein et al (2008) that, in a static, unimodal fitness landscape, individual learning actually serves to slow convergence rates.

With social learning, convergence times are markedly more rapid, reaching a mean fitness of 0.5 in less than half the time as evolution or evolution plus learning.

### Static environment with single perturbation

Here, the scenario was repeated as per the Static Environment case, with with an environmental perturbation induced at step 10000: each of its bits were flipped according to a

probability  $p = 0.5$ . As indicated in Figure 3, this change results in a temporary increase in social and exploratory learners, bringing up phenotypic fitness through plasticity whilst evolution takes time to work out the necessary series of mutations.

Figure 3: A single perturbation occurs at  $t = 10000$ . Subsequently, agents are selected for increased social and exploratory learning tendencies.

Figure 4: Genotypic and phenotypic fitness after perturbations.

This further demonstrates Baldwin-like phenomena, and moreover with a *social* focus: whilst a small proportion of individuals respond to environmental change by switching to individual exploration, the predominant trend is to rely on social learning, observing the behaviour of others to maximise fitness.

### Fluctuating environment

We now extend the above by introducing irregular environmental fluctuations. Each time step, a single bit of the environmental task may be toggled, according to a small probability  $p_{switch}$ . A value of  $p_{switch} = 0.01$  reflects an ex-

Figure 5: With a regularly fluctuating environment ( $p_{switch} = 0.01$ ), a social learning strategy is more frequently adopted.

Figure 6: With a higher reliance on phenotypic plasticity, genetic selection pressure is lower, and so genotypic constitution drifts.

pected period of 100 timesteps between fluctuations. With an initial metabolism  $\Omega_0 = 10$  and a typical  $\Delta\Omega = 0.5$ , the environment could be expected to fluctuate once every 5 agent-lifespans.

The optimal combination of strategies is markedly different than in a fixed environment (Figures 5 and 6). Social learning dominates, reflecting the benefit of a faster adaptive rate with changing fitness targets.

Convergence patterns are also markedly different (Figure 7). In a rapidly changing environment ( $p_{switch} = 0.005$ ), no strategy attains a mean fitness of above 0.7: even with the ability to mimic successful peers, it is difficult to maintain a high performance level in the face of continuous change. Social learning is frontrunner once more, with  $b_{evo} + b_{exp}$  significantly outperforming pure evolution. This reflects the advantage in random trials when an organism's genome is lagging behind the rate of change of its environ-

Figure 7: Convergence rates are markedly different within a fluctuating environment ( $p_{switch} = 0.005$ ).

ment.

### Environmental rate and complexity

To gain fuller insight into the relative strengths of individual, social and exploratory learning in fluctuating environments, we carried out an array of simulations over a range of rates of change ( $p_{switch} \in [5 \times 10^{-6}, 0.5]$ ) and environmental complexities ( $B \in [1, 2048]$ ). Each permutation of  $p_{switch}$  and  $B$  was executed for  $10^5$  timesteps, and a snapshot taken of the final distribution of behavioural traits. These are mapped in Figure 8, with the dominance of each trait demonstrated by its share of the pie chart at the given (*complexity, rate*) combination.

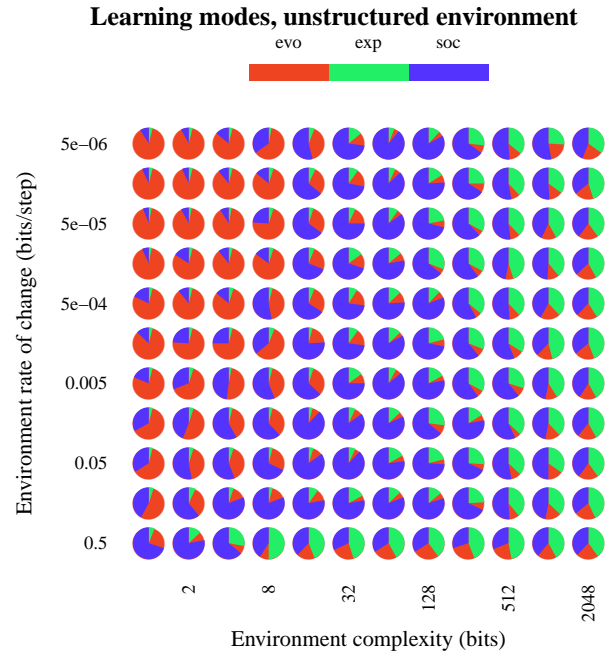

Figure 8: Dominant learning modes at equilibrium, varying dimensionality and rate of change of environment.

Figure 9: Ring of environmental ‘cells’. Tasks are numbered according to Gray code: note that adjacent cells have 1 bit difference.

At low rates of change and in simple environments, the population demonstrates a significantly greater mean growth rate, with a clear prevalence of  $b_{evo}$ . As *either* rate or complexity increase, strategies become more mixed, with a trend towards social learning at median values of each. A greater amount of noise in the results suggests that selection pressures per are weaker, leading to more vulnerability to stochastic variation.

At very high rates of change or complexity, a sudden increase of  $b_{exp}$  dominance is evident. This is relatively simple to interpret in the former case: if the environment is changing faster than information can percolate through a social group, then even social learning is inferior to individual trial and error.

The benefit of learning in very complex environments is less clear; even in a virtually static environment ( $p_{switch} = 5 \times 10^{-6}$ ), exploration exceeds innate strategies for  $B = 2048$ . Analysis reveals that the fitness ( $\Delta\Omega$ ) in these regimes is uniformly low: given the rapid fitness falloff due to  $\alpha$ , neither evolution nor social learning are fit to find suitable values. With such a large parameter space, the optimal resort is simply bit-wise trial and error.

### Structured environment

We now extend the model by introducing a form of spatial structure. The single environment is replaced by a 1-dimensional ring of  $L$  environmental ‘cells’, each with a distinct population and set of tasks (Figure 9). Inhabitants of each cell can only interact with each other. As before, the size of the total metapopulation remains constant at  $N$ .

Each environmental cell has a single neighbour on each side, with the rightmost cell wrapping around to the leftmost. To introduce correlation between the task structure of neighbouring cells, integer sequences were produced us-

ing Gray code, a base-2 numeric encoding in which any two adjacent integers have a Hamming distance of 1. A further property of Gray code sequences is that they are cyclical, with the first and final integer of any  $2^N$ -length sequence also one bit apart. It is possible, therefore, to produce integer rings with pairwise Hamming distance of 1.

During a timestep, a agents may move from their current location to a neighbouring cell with a small probability  $p_{move}$ . Evolutionary and individual learning are unaffected; social learning, however, is now restricted to exemplars within the agent’s current location.

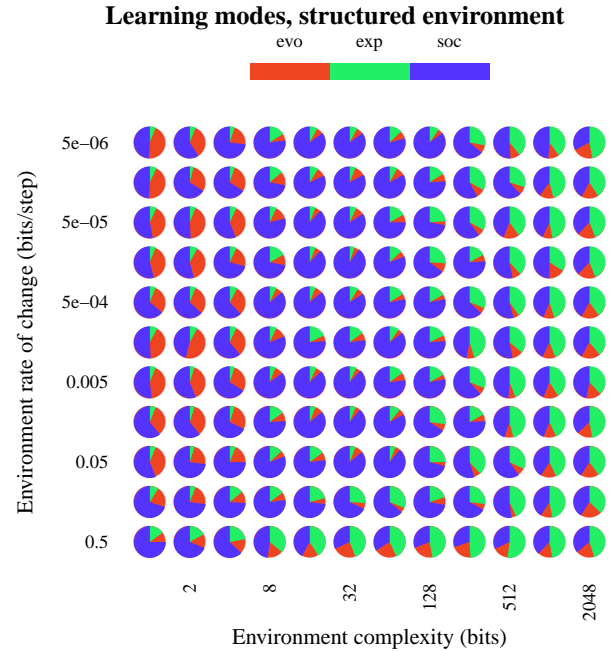

Figure 10: Dominant learning behaviours in a structured environment with migration.

From Figure 10, we can see that the overall distribution of learning patterns is similar: in static, simple environments, innate behaviour is commonplace, moving towards social learning in more complex and fluctuating contexts.

With rapid fluctuations, exploratory learning still excels, but it appears to have slightly less prevalence in environments with a large  $B$  value. This appears to be due to what we will call the “*local specialist*” effect: in a well-mixed, complex environment, there are a large range of behaviours to mimic, drawn from a large variety of sources. Even if we select our exemplar wisely, we may still mimic the wrong behaviour, as they too will be employing random search to test out new tasks.

In a structured environment, conversely, we have smaller number of local neighbours to mimic. With the roulette-wheel mechanism used to select exemplars, a smaller population also means a higher likelihood of selecting an highly-

ranked target. Combined with the fact that selection pressure still operates by removing the weakest agents of the *global* population, this means that positive behaviours are disseminated and adopted rapidly within individual cells, giving rise to social ‘specialist’ cliques.

### Structured environment with migration

In this scenario, we remove environmental fluctuations, and instead vary  $p_{move}$ : the rate at which migration occurs. Figure 11 depicts this new distribution, with its Y-axis representing the rate of migration, over the same range as the fluctuation rate was previously plotted. The only variation that an agent will experience in its environment is when it moves from cell to neighbouring cell, so this can effectively be considered analogous to our previous environmental fluctuations.

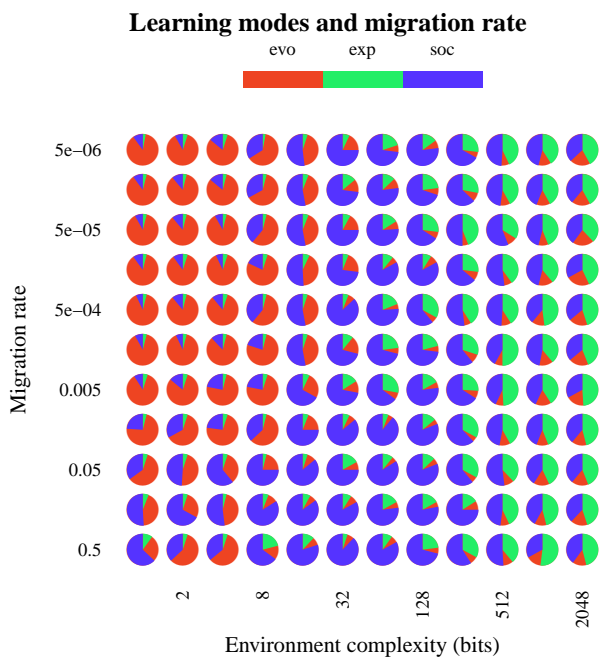

Figure 11: Dominant learning behaviours by migration rate and environmental complexity.

Learning strategies do not appear to correlate significantly with movement rates, despite the fact that movement between cells *does* effectively change the environment that an agent experiences. However, a significant difference takes place at high movement rates. Rather than resorting to individual trial and error, agents make greater use of social learning. This may be interpreted as a more focused version of the local specialist effect; in a static environment with frequent migration, we would expect the rapid dissemination of local knowledge to become of paramount importance.

In other words, if an agent is commonly moving from environment to environment, the most effective way to obtain

information about novel functions is to mimic the locals. This has both logical and biological plausibility.

### Discussion

We have seen that three discrete regimes appear within varying classes of environment, each favouring different forms of learning. Within static environments, innate behaviour excels; within rapidly-changing environment, exploratory behaviour comes to the fore. Social behaviour, conversely, fills the gap between the two.

Beyond this, social transmission serves to inform and drive subsequent evolutionary behaviour, with what Papineau (2005) terms a “social Baldwin effect”. Our results suggest that this may play a pivotal role in the aftermath of major environmental changes – which, in ecosystems wherein organisms act as background to other organisms, may also correspond to the aftermath of major *ecological* changes.

In a structured environment, we have seen that successful behaviours are disseminated rapidly, due to reliance on smaller, focused groups of ‘specialists’ in each location. With greater environmental complexity, these local effects are amplified yet further.

### Methods

Simulation results are averaged over 25 iterations to minimise stochastic fluctuations. Default variable values are given below.

Variable	Value	Comments
$N$	256	Population size
$L$	32	Number of spatial locations
$B$	32	Number of bits per task
$\Omega_0$	10	Initial metabolic state
$\alpha$	0.1	Rate of fitness dropoff based on task proximity
$\beta$	1	Maximum number of bits learned per timestep
$\mu$	0.01	s.d. of mutation as applied to $b_{evo}, b_{exp}, b_{soc}$
$p_{switch}$	0.01	Probability of a single environmental fluctuation
$p_{noise}$	0.25	Probability of incorrect observation during mimicking
$p_{mut}$	0.01	Probability of sustaining a mutation per gene
$p_{move}$	0.1	Probability of migrating to a neighbouring cell

### Acknowledgements

The authors would like to thank Christophe Rhodes, Tim Taylor and Mark d’Inverno for their insightful comments.

# Evolutionary Dynamics of GAs in a Simple Model with Dynamical Environment and Neutrality

Yoshiaki Katada<sup>1</sup>

<sup>1</sup>Setsunan University, Osaka 572-8508, JAPAN  
katada @ ele.setsunan.ac.jp

## Abstract

Biological organisms have various mechanisms of coping with the dynamical environments in which they live. Recent papers in computational biology show that individuals reside in deferent regions of neutral networks according to environmental variation. This work investigated evolutionary dynamics of GAs in dynamical environments with neutrality using a simple model. The evolutionary dynamics observed were consistent with those observed in the experiments of biological evolution, confirming that the genotype distributions change depending on the rates of environmental variation as well as mutation.

## Introduction

The Neutral theory (Kimura, 1983) was developed by Motoo Kimura in the 1960s. Neutrality is caused by highly redundant mappings from genotype to phenotype or from phenotype to fitness. Based on this, it was reported that biological organisms make good use of genetic mechanisms which do not appear in phenotype to adapt to environmental variations on the evolutionary time scale.

The effects of neutrality has been discussed so much in the EC community especially since Harvey introduced the concept of neutral networks (Harvey and Thompson, 1996). These researches can be classified into two types as follows. The former researches are based on redundant mappings from phenotype to fitness, where neutral networks are included in a problem itself. Examples would be the evolution of neural network controllers in robotics (Harvey, 1997; Smith et al., 2001) and on-chip electronic circuit evolution (Thompson, 1996; Vassilev et al., 2000). In these researches, evolutionary dynamics are investigated (Barnett, 1997; Newman and Engelhardt, 1998; van Nimwegen et al., 1999; Katada et al., 2004) or the degree of neutrality in fitness landscapes is estimated (Smith et al., 2002; Katada and Ohkura, 2006). The latter based on redundant mappings from genotype to phenotype, where redundancy, that is, neutrality has been intentionally incorporated by EC researchers for problems where redundancy is largely absent to improve the performance of artificial evolution (Ohkura and Ueda,

1999; Ebner et al., 2001; Knowles and Watson, 2002; Rothlauf and Goldberg, 2003).

To the best of my knowledge, in the former type of research, neither evolutionary dynamics nor useful genetic operators in *dynamical environment* has been investigated. Independently of neutrality, representations of polyploid model in dynamical environment have been investigated where useful genes in previous environments are preserved in some kind of memories (Branke, 2001). Apparently, the feature of polyploidy is a redundant genetic material, that is, redundant mappings from genotype to phenotype. However, it seems likely that there is no research that investigate this from the view point of neutrality.

GP, whose evolved programs include many introns and functionally redundant parts, would be classified into the former research. That is why some GP researchers have claimed the importance of neutrality in recent years (Yu and Miller, 2006; Miller, 2009; Vanneschi, 2009).

Recent papers in computational biology show that individuals reside in deferent regions of neutral networks according to environmental variation. Meyers et al. (2005) analyzed evolution in a periodically changing environment using a simple model and a codon model where a locus has several alleles and some of them are functionally equal, and reported as follows: When environmental variations are rare, most individuals are located in the center of the neutral network with the highest fitness value in each environment preparing for detrimental mutation (Fig. 1(a)). This phenomenon is called *genetic robustness*. When the rates of environmental variation are intermediate, most individuals are located in the edge of the neutral network in order to obtain a new phenotype which can adapt to an alternating environment with a few mutations (Fig. 1(b)). This is called *genetic potential*. When the rates of environmental variation are high, they are settled in a phenotype with an intermediate fitness value in both environments (Fig. 1(c)). This would mean that they have tolerances and adaptivity for both environments but would never go to extremes. This is called *organismal flexibility*.

Based on these knowledges, Yu (2007) investigated evolu-

Figure 1: Distribution of individuals due to environmental variation

tionary dynamics of the GP in a boolean parity problem under environmental variations. It was reported that when the variation rate is high, the length of a program tree became long, that is, the effective mutation rate per individual became high, and when the variation rate is low, the length became short, that is, the effective mutation rate per individual became low. Yu (2007) claimed that when the variation rate becomes high, individuals of the GP tend to be located in the edge of the neutral network because the effective mutation rate per individual becomes high and individuals easily change their phenotype. However, we have trouble defining a neutral network on GPs due to its representation. Therefore, it is difficult to discuss directly the consistency of the obtained results in the GP to the computational biology because we need the concept of location on a neutral network for them.

Based on these results, the question arises as to whether we can get the same kind of dynamics of GAs in dynamical environments with neutrality because neutral networks have been found in GAs with highly redundant mappings from phenotype to fitness. In the case of GAs with redundant mappings from genotype to phenotype (including polyploidy), we would get the same kind of results on the “GPs” mentioned above because it would be difficult for the GAs to devise a neutral network<sup>1</sup> and effective mutation rates of

<sup>1</sup>It is possible to define a neutral network in GAs with redundant

them are variable.

This paper focuses on the former case, where GAs with redundant mappings from phenotype to fitness (more precisely, genotype to fitness) that can form neutral networks and investigates evolutionary dynamics of them in a simple model by varying the rates of environmental variation and the mutation rate. The paper is organized as follows. The next section describes a neutral network in a mathematical form. Section III describes a simple model of dynamical environments with neutrality where evolutionary dynamics of GAs is investigated. Section IV gives the results of our computer simulations. Section V discusses the consistencies with the results obtained in computational biology. Conclusions are given in the last section.

### A Formal Definition of a Neutral Network

Katada and Ohkura (2009) defined a neutral network in a mathematical formula. The details are as follows;

In this study, it is assumed that genotypes are represented as binary strings and the length of them is fixed. Thus, the genetic distance between two different genotypes ( $x^g, y^g \in \Phi_g, x^g \neq y^g, \Phi_g$ : the set of genotypes determined by the length of the genotype,  $l$ ) is described by the Hamming dis-

mappings from genotype to phenotype (See the next section) but difficult to make neutral networks emerge from genotype space in which neutrality is intentionally incorporated as mentioned earlier.

tance between them,  $H(x^g, y^g)$ . Thus,  $\min H(x^g, y^g)$  is the smallest unit of mutation. For binary representations,  $\min H(x^g, y^g) = 1$ .

Based on the above consideration, I describe a neutral network caused by redundant mappings from genotype to phenotype in a mathematical form. At first, two individuals,  $x^g$  and  $z^g$ , are connected,  $x^g \sim z^g$ , if there exists  $\{x_i^g\}_{i=0}^n \subset \Phi_g$ , s.t.

1.  $x^g = x_0^g, z^g = x_n^g$ ,
2.  $f_g(x_i^g) = f_g(x_{i+1}^g)$ ,
3.  $H(x_i^g, x_{i+1}^g) = 1$ ,

where  $f_g$  is the mapping from genotype to phenotype,  $f_g : \Phi_g \rightarrow \Phi_p$ , and assumed to be surjective and not injective.  $\Phi_p$  is defined as the set of phenotypes.

Thus, a neutral network of a genotype  $z^g$  is

$$\Phi_g'(z^g) = \{x^g \in \Phi_g | x^g \sim z^g\}. \quad (1)$$

We can extend this definition to redundant mappings from phenotype to fitness.

Two individuals,  $x^g$  and  $z^g$ , are connected,  $x^g \sim z^g$ , if there exists  $\{x_i^g\}_{i=0}^n \subset \Phi_g$ , s.t.

1.  $x^g = x_0^g, z^g = x_n^g$ ,
2.  $(f_p \circ f_g)(x_i^g) = (f_p \circ f_g)(x_{i+1}^g)$ ,
3.  $H(x_i^g, x_{i+1}^g) = 1$ ,

where  $f_p$  is the mapping from phenotype to fitness,  $f_p : \Phi_p \rightarrow \Phi_f$ , and assumed to be surjective and not injective.  $\Phi_f$  is defined as the set of fitness values. Addition to this assumption, there would be two cases on  $f_g$ , which is either bijective, or surjective and not injective. In both cases, however,  $f_p \circ f_g$  is surjective and not injective only if  $f_p$  is surjective and not injective. Thus, a neutral network of a genotype  $z^g$  is described in the both cases as follows:

$$\Phi_g^*(z^g) = \{x^g \in \Phi_g | x^g \sim z^g\}. \quad (2)$$

These may seem to be cumbersome at first. But this elegant definition allows us to understand clearly a setting for computational experiments in the following sections.

### Simple Model with Dynamical Environment and Neutrality

In this study, computer simulations were conducted in order to compare evolutionary dynamics of GAs with those observed in the experiments of biological evolution (Meyers et al., 2005). For performing simple analysis, the length of a string is set at 4. According to the setting given in the reference (Meyers et al., 2005), a set of genotypes is defined

Table 1: Set of genotype

Genotype ( $g_i$ )	ID ( $i$ )	Nickname
1011	0	NN1-c
1111	1	NN1-e1
1101	2	NN1-e2
1001	3	NN1-e3
1010	4	NN1-e4
0011	5	NN1-e5
1110	6	INV-1
1000	7	INV-2
0111	8	INV-3
0001	9	INV-4
0100	10	NN2-c
0110	11	NN2-e1
0010	12	NN2-e2
0000	13	NN2-e3
0101	14	NN2-e4
1100	15	NN2-e5

Figure 2: Space of genotype

as Table 1 and Fig. 2. The fitness function is also defined as follows:

$$w_A(g_i) = \begin{cases} 1 + s & (0 \leq i \leq 5) \\ 1 + ks & (6 \leq i \leq 9) \\ 1 & (10 \leq i \leq 15) \end{cases} \quad (3)$$

$$w_B(g_i) = \begin{cases} 1 & (0 \leq i \leq 5) \\ 1 + ks & (6 \leq i \leq 9) \\ 1 + s & (10 \leq i \leq 15), \end{cases} \quad (4)$$

where  $w_A$  and  $w_B$  are fitness functions for environments  $E_A$  and  $E_B$ , respectively.  $s$  and  $k$  ( $s > 0, 0 \leq k \leq 1$ ) are the parameters to adjust the highest and intermediate fitness values given to certain genotypes in each environment, respectively. These parameters were set as follows:  $s = 1, k = 0.5$  following the recommendations given in (Meyers et al., 2005).

In this function, a fitness value is assigned to a genotype directly so no phenotype is defined. Thus, it is considered that  $f_g$  is bijective as mentioned in the previous section. Then  $f_p \circ f_g$  is investigated. According to the definition of a neutral network (Eq.(2)), the genotypes with  $i = 0, \dots, 5$

and those with  $i = 10, \dots, 15$  form a neutral network in both environments,  $E_A$  and  $E_B$ , respectively. These neutral networks show the highest fitness value and lowest fitness value in Eqs. (3) and (4), respectively. In each neutral network, a genotype which does not mutate out of its neutral network with 1 bit is considered to be located at the center of its neutral network (NN1-c and NN2-c in Table 1) while a genotype which does mutate out of its neutral network with 1 bit is considered to be located on the edge of its neutral network (NN1-e and NN2-e in Table 1). For this setting, each neutral network has only one genotype which is located at the center of it. The other genotypes ( $i = 6, \dots, 9$ ) show the intermediate fitness value but do not form any neutral networks.

### Computer Simulation

In this computer simulations, the GA (Goldberg, 1989) were adopted to evolve individuals in both the environments,  $E_A$  and  $E_B$ , mentioned in the previous section. The length of the genotype is 4 as also mentioned in the previous section. The population size was set at 10 according to the setting in (Yu, 2007). In this study, computer simulations were conducted in order to investigate evolutionary dynamics of GAs in a simple model by varying the rates of environmental variation and the mutation rate. Thus, the genetic operations for the GA were standard bit mutation and fitness proportionate reproduction. The per-bit mutation rate,  $q$ , was set as follows:  $q \in \{0.025, 0.05, 0.1, 0.2, 0.25, 0.3, 0.4, 0.5\}$ . Each run lasted 2,000 generations. The initial environment was set at  $E_A$ . The environment was alternately switched every  $\lambda$  generations as follows:  $E_A \rightarrow E_B \rightarrow E_A \rightarrow \dots$ . For each run,  $\lambda$  was set between 1 and 1000 as follows:  $\lambda \in \{1, 2, \dots, 20, 30, \dots, 100, 200, \dots, 1000\}$ . 50 independent runs were conducted for each parameter. All results were averaged over 50 runs.

Fig. 3 shows the ratio of the individuals with the highest fitness value,  $f = 1 + s$ , the intermediate value,  $f = 1 + ks$ , and the lowest value,  $f = 1$  with  $q = 0.025$  and  $\lambda = \{2, 10, 100\}$ <sup>2</sup>. For each  $\lambda$ , a population adapted to a new environment to produce the individuals with the highest fitness value. However, not all individuals converged to the highest fitness value.

The distribution of the individuals were dependent on  $\lambda$ . For short variable periods (e.g.  $\lambda = 2$  in Fig. 3(a)), more than the half of individuals never had the highest fitness value and the individuals with the intermediate fitness value were dominant (approximately 45-50 %). This is because environmental variation was so rapid that there was not enough time for the individuals to adapt to each environment. This might be considered that evolution supported the individuals which can adapt faster to rapid environmental

<sup>2</sup>I plot only the first 100 generations for  $\lambda = 2, 10$  and the first 400 generations for  $\lambda = 100$  because the similar patterns were repeatedly observed after the generations.

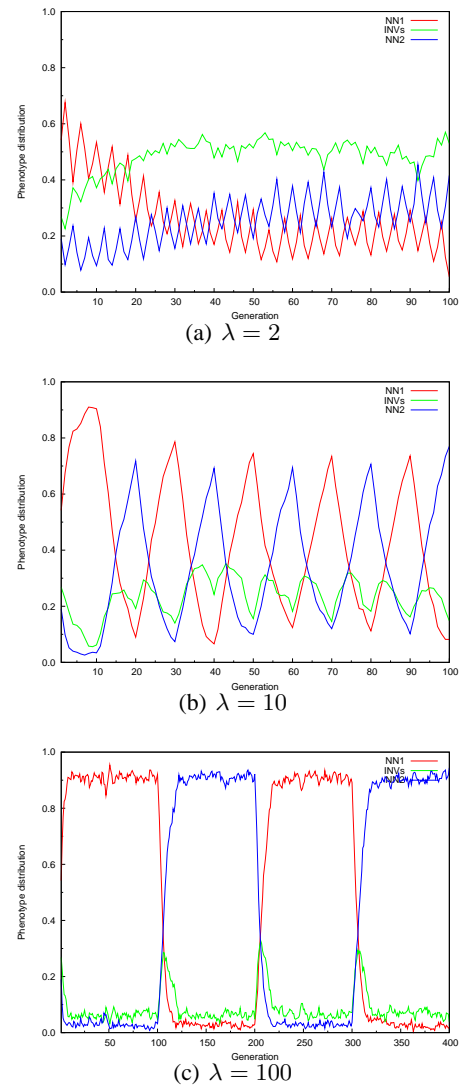

Figure 3: Individual distributions at each generation ( $q = 0.025$ )

variations, that is, the individuals which can mutate easily to the one with the highest fitness value. Such individuals with the intermediate fitness value would be considered to be *organismal flexibility* as mentioned earlier.

For longer variable periods (e.g.  $\lambda = 10$  in Fig. 3(b)), the number of the individuals with the highest fitness value increased while the number of the ones with the intermediate fitness value decreased. For even longer variable periods (e.g.  $\lambda = 100$  in Fig. 3(c)), there was enough time for the individuals to adapt to each environment and the individuals with the highest fitness value became dominant. In Fig. 3, we can not find “where” the individuals are located in the neutral network with the highest fitness. The more details can be found in Figs. 4 and 5.

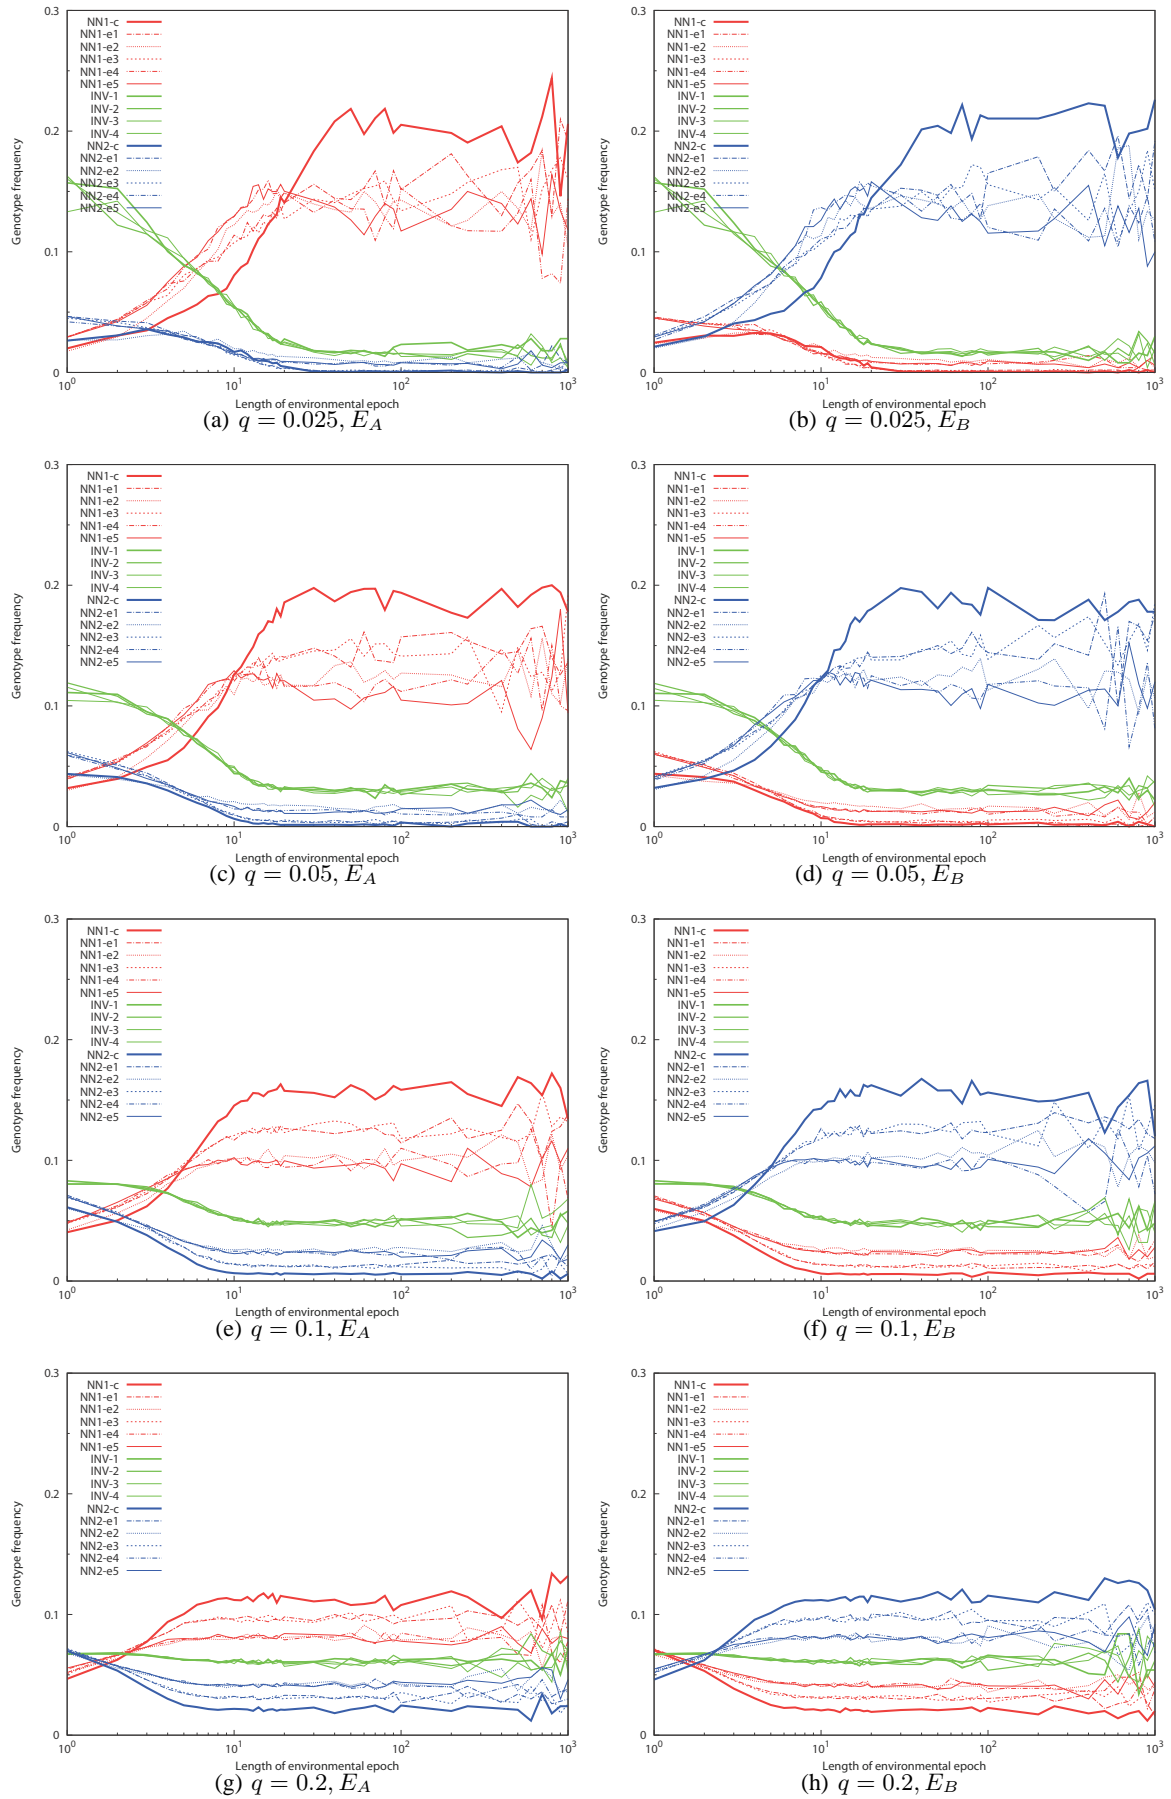

Figure 4: Individual distributions over variable periods for  $E_A$  and  $E_B$  ( $0.025 \leq q \leq 0.2$ )

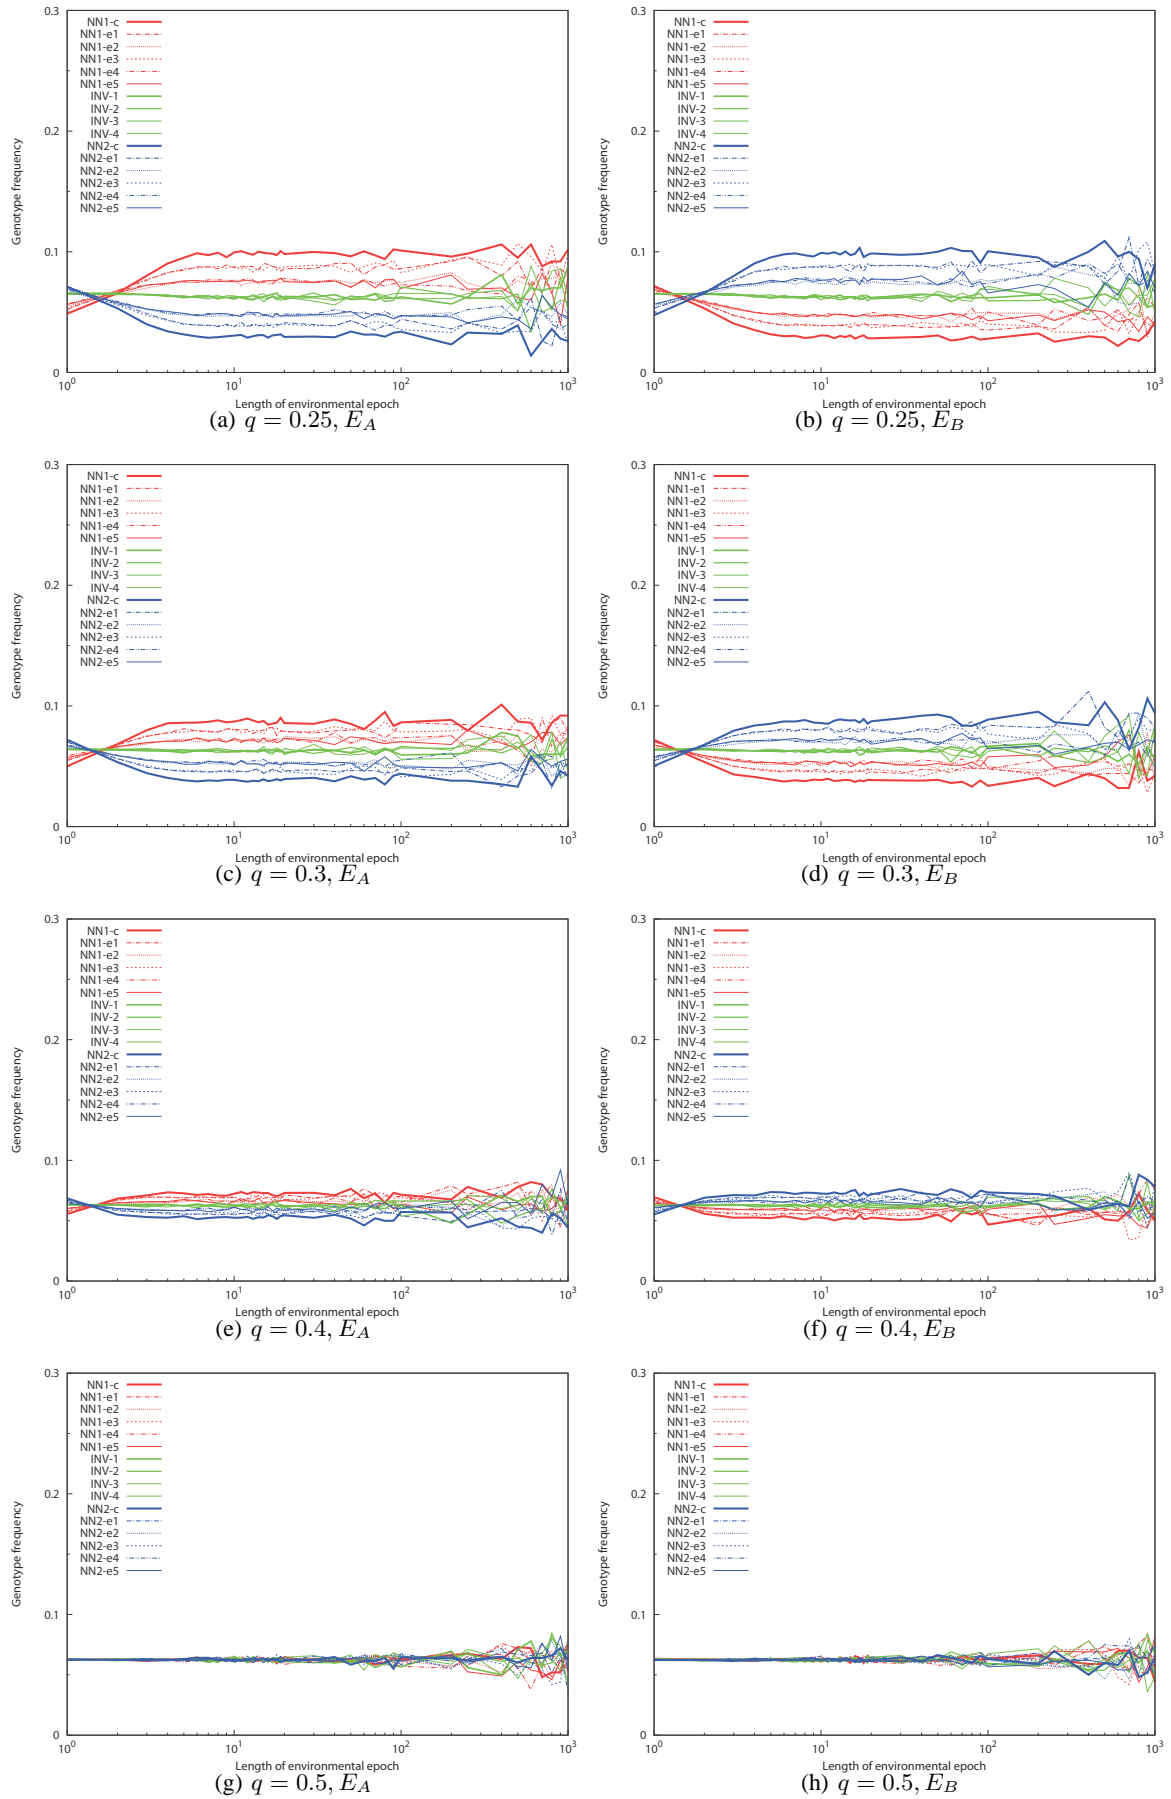

Figure 5: Individual distributions over variable periods for  $E_A$  and  $E_B$  ( $0.25 \leq q \leq 0.5$ )

Figs. 4 and 5 show the ratios of the genotypes over  $\lambda$ s for each  $q$ . Here, the ratio of a genotype was calculated by dividing the sum of the values just before generations when the environment was switched with the number of switching environments and the number of runs. The bold line shows the ratio of the genotype which is located at the center of its neutral network and the thin line shows the one of the genotype which is located on the edge of its neutral network. The horizontal axis is based on a logarithmic scale.

Over the mutation rate range  $0.025 \leq q \leq 0.1$  (Fig. 4(a)-4(f)), for long variable periods, the ratio of the genotype which was located at the center of the neutral network with the highest fitness value was larger than the ones of the other genotypes in both environments. The genotypes which were located on the edge of the neutral network attained the second-largest rate. For shorter variable periods, the ratios of the genotypes which were located on the edge of the neutral network were larger than the ones of the other genotypes. Among them, the ratios were different due to their own locations on the edge. Thus, the ratios of them which are adjacent to not only the genotypes with the intermediate fitness value but also the ones with the lowest fitness value were larger. The variable period range in which this phenomenon appears decreased with the increase of  $q$ . For even shorter variable periods (approximately  $1 \leq \lambda \leq 3$ ), the ratio of the genotype with the intermediate fitness value was largest. For these shortest variable periods, the same result was obtained in Fig. 3(a).

Over the mutation rate range  $0.2 \leq q \leq 0.4$  (Fig. 4(g)-4(h), Fig. 5(a)-5(f)), for long variable periods, the ratios of the genotypes which were located at the center of the neutral network and on the edge of it were large in this order. However, these values were not beyond 0.1. For even shorter variable periods, the ratios of the genotypes with the lowest fitness value were a few larger than or equal to the ones with the highest and intermediate fitness value.

For  $q = 0.5$  (Fig. 5(g)-5(h)), there was no significant difference between the genotypes, which were distributed randomly.

## Discussion

In the earlier section, the loosely defined phenomena, *genetic robustness*, *genetic potential* and *organismal flexibility*, were cited. In order to discuss the results obtained in the previous section, those are more accurately defined as follows: *genetic robustness*: the state where the ratio of the genotype which is located at the center of the neutral network with the highest fitness value is largest in the environment,  $E_A$  or  $E_B$ . *genetic potential*: the state where the ratio of the genotype which is located on the edge of the neutral network is largest in each environment. *organismal flexibility*: the state where the ratio of the genotype with the intermediate fitness value is largest.

According to these definitions, we can find such phase

transitions as organismal flexibility  $\rightarrow$  genetic potential  $\rightarrow$  genetic robustness for  $q \leq 0.1$ , and organismal flexibility  $\rightarrow$  genetic robustness for  $0.2 \leq q \leq 0.4$  in Figs. 4 and 5 with the increase of the variable period. Meyers et al. (2005) described that we can find *genetic potential* in a much wider variable period range when the mutation rate decreases because it takes more time to reach the state, *genetic robustness*. This is consistent with the results in Figs. 4(a)-4(f) in which we can find *genetic potential* in the ranges,  $6 \leq \lambda \leq 20$  for  $q = 0.025$ ,  $5 \leq \lambda \leq 10$  for  $q = 0.05$  and,  $3 \leq \lambda \leq 5$  for  $q = 0.1$ . Meyers et al. did not mention *organismal flexibility* for the high mutation rates. For the results obtained in this study, we can not find any *organismal flexibility* when the mutation rate was high. This would be considered to be affected by the *error threshold* on the mutation rate (Kauffman, 1995); As the mutation rate increases, the population gradually loses the current individuals. At a certain critical mutation rate, the individuals become distributed randomly.

Meyers et al. (2005) also claimed that the mutation rate per locus does not need to be variable if the phenotypical mutation rate or the effective mutation rate per genotype is variable as opposed to the argument that the variable mutation rate per locus is important for adaptation to environmental variations. This argument would be explained as follows. When the mutation rate per locus is low, individuals must change their phenotypes (or obtain the higher fitness value) as soon as possible in order to adapt to environmental variation. Thus, the individuals which are located on the edge of the neutral network are supported. When the mutation rate per locus is high, individuals can change quickly their phenotypes even though they are located at the center of the neutral network. Therefore, the dominance of the individuals which are located on the edge of the neutral network becomes invisible at such a mutation rate.

## Conclusions

This study investigated evolutionary dynamics of GAs in a simple model by varying the rates of environmental variation and the mutation rate. The results can be summarized as follows:

- Two or three phase transitions were observed over the variable period range. Especially when the mutation rate is low, the results were consistent with the results obtained in computational biology.
- For long variable periods, the frequency of the genotype which was located at the center of the neutral network with the highest fitness value was largest in the population.
- For shorter variable periods, the frequency of the genotype which was located on the edge of the neutral network was largest.

- For even shorter variable periods, the frequency of the genotype with the intermediate fitness value was largest.

In this study, four-bit binary strings were used to provide simple explanatory examples. Additionally, a small population size and an alternating environment were set. Further computer simulations will be conducted in order to investigate whether these observations are consistent with more complex settings (Yang et al., 2007). Another future direction would be an analytical approach due to the simplicity of the model.

# Why Aren't Protein Residue Networks Smaller Worlds

Susan Khor<sup>1</sup>

<sup>1</sup>Montréal, Canada  
slc.khor@gmail.com

## Abstract

In this paper, *in silico* experiments are performed to investigate why protein residue networks (PRNs), i.e. networks induced by spatial contacts between amino acid residues of a protein, do not have shorter average path lengths (APLs) in spite of their importance to protein folding. We find that shorter average inter-nodal distances does not necessarily imply better search performance, i.e. more successful protein folding. Search performance of a zero-temperature Metropolis style hill-climber was not significantly improved by randomizing only the long-range links of PRNs even though such randomization significantly reduces APLs of PRNs while retaining much of the clustering and positive degree-degree correlation inherent in PRNs. However, this result is contingent upon the optimization function. We found that the optimization function which places PRNs in a favorable spot in the space of possible network configurations considered in this paper parallels an existing view in protein folding theory that neither short-range nor long-range interactions dominate the protein folding process. These findings suggest the existence of explanations, other than the excluded volume argument, beneath the topological limits of PRNs.<sup>1</sup>

## Introduction

Breaking the code underlying protein folding has remained an intellectually tantalizing puzzle as well as a problem of great practical significance. Everything a protein requires for correct folding under normal circumstances appears to be embedded in its amino-acid sequence (Afinsen 1973), although a minority rely on the aid of water and chaperone molecules. Due to the large sizes that amino-acid sequences can take, a random search approach to protein folding is deemed infeasible for practical biological purposes (Levinthal 1969). However, an argument based on separability of the protein folding problem, i.e. that the problem can be separated into parts which can then be solved independently and assembled into an optimal solution<sup>2</sup>, has been conceived as a way out of Levinthal's paradox (Zwanzig *et al* 1992; Karplus 1997). This argument is supported by some sections of protein

sequences having a propensity to fold to their native secondary structures.

In general, protein folding is a process that occurs in stages. What essentially begins as a linear hetero-polymer (organized as a backbone with protruding side chain groups) obtains local structure in the form of secondary alpha helices and beta sheets and finally global structure as the secondary structures arrange themselves compactly in three dimensions. For a long time, this spontaneous biological self-organization has been attributed to various inter-atomic physical forces and chemical constraints impacting a protein molecule. However, in the last decade or so, another theory based on the network topology of a protein's native state has blossomed. In this other theory, a network view of protein molecules (mostly in their native states) is adopted.

The general recipe to transform a protein molecule into a network is to represent amino acid residues ( $C_\alpha$  or  $C_\beta$ ) as nodes, and contact (spatial, non-covalent) distances between pairs of amino acid residues below a certain threshold as links. Such *protein residue networks* (PRN) are constructed from the Cartesian coordinates of amino acid residues of protein molecules stored in the Protein Data Bank (PDB) (Berman *et al* 2000). There are variations to the general recipe however. For instance, a PRN may represent several non-homologous proteins rather than a single protein, e.g. the protein contact map in (Vendruscolo *et al* 2002). PRNs may also represent different aspects (e.g. surface or core), states (e.g. native or transitional), structural classes (e.g.  $\alpha$ ,  $\beta$ ,  $\alpha+\beta$  or  $\alpha/\beta$ ), or types (e.g. globular or fibrous) of proteins (e.g. Atilgan *et al* 2004). Further, the nodes and links of PRNs may carry different meanings, e.g. the atoms of the side chain group of an amino acid may be included so that a node may represent more than one atom and multiple links between nodes or weighted links are allowed (Green and Higman 2003).

By examining PRNs, researchers have compiled a list of topological characteristics shared by a diverse (in terms of structural class, homology and taxon) set of proteins and speculated on the reasons for the observed topological characteristics in relation to protein folding. A common feature of protein residue networks is their *small-world* nature, i.e. they have lattice like clustering coefficients but random graph like diameters and average path lengths (Watts and Strogatz 1998). The need for rapid communication between amino acid residues to facilitate *interaction cooperativity* crucial for protein folding is frequently cited as the reason for the small-world feature of PRNs (Vendruscolo *et al* 2002; Dokholyan *et al* 2002; Atilgan *et al* 2004; Del Sol *et al* 2006). PRNs are also reported to exhibit high assortativity values

<sup>1</sup> This is an independent research paper, part of which was completed during the author's stay at Collegium Budapest, Hungary who generously provided the computer resources for most of the experiments. At the time this paper was prepared, the author is a post-doctoral researcher in Montréal, Canada.

<sup>2</sup> For a more colourful description, see Herbert Simon's parable of the two watchmakers in *The Sciences of the Artificial*, 1969 MIT Press.

which can be related to protein folding speeds (Bagler and Sinha 2007). We discuss network characteristics of PRNs further on.

In this paper, we set out to understand why, given the assumed importance of rapid inter-residue communication to protein folding, PRNs are not smaller-worlds or equivalently do not have shorter average shortest path lengths. We address this question from a search perspective, which is not unusual given the common formulation of protein folding as a search problem. We define a spin-glass like problem on a PRN and use the performance of a local search (a hill-climber in the fashion of the Metropolis algorithm with zero probability of assuming a higher temperature configuration) to assess the effect of changes in network topology, specifically average path length (APL), on search performance. The experiments are conducted under several conditions, motivated by existing literature on protein folding theory.

## Method

### Protein residue network construction

Our PRN has  $N$  nodes (one for each amino acid of a protein) and  $M$  links. An undirected link is placed between a pair of nodes representing the  $C\alpha$  atom of amino acids when the node pair is situated less than  $7\text{\AA}$  apart from each other. The small-world property of PRNs is not overly sensitive to the choice of this threshold value (Bartoli *et al* 2007). Distance between node pairs is the Euclidean distance between their 3D Cartesian coordinates obtained from the Protein Data Bank or PDB (Berman *et al* 2000). The  $M$  links are partitioned into two sets: long-range links ( $LE$ ) and short-range links ( $SE$ ). A link between nodes  $x$  and  $y$  is classified as *long-range* if their absolute distance on the amino acid sequence chain is more than 9 (Green and Higman 2003). Long-range links connect amino acids which are distant in the primary structure but are in close spatial proximity in the tertiary structure.

### Test data set

A PRN is built for each protein in the GH64 dataset (Figures 1&2) which was selected from literature surveyed, specifically (Green and Higman 2003). The dataset encompass proteins from different protein classes, fold types and branches of life. Proteins which did not form a single connected component (i.e. 1cuk and 1ho4), or had unusually high link density (i.e. 1feo) in its PRN were excluded from the dataset. So too were proteins with more nodes in their PRN than their DSSP output (Kabsch and Sander 1983) (i.e. 2hmz and 1epf). We use the output from DSSP (Dictionary of Protein Secondary Structure) as globally optimal strings in our search problem. If the reverse situation occurs, the DSSP output is truncated. A second dataset, EVA132, is used to increase confidence of key results in this paper. The EVA132 protein dataset was extracted from the list of 3477 unique chains archived by EVA (Rost, 1999). 200 proteins were selected at random from this list, with no overlap with GH64. PRNs for these 200 proteins were constructed and selected in the same manner as GH64, yielding 132 well-formed PRNs. EVA132 PRNs possess similar network characteristics as

GH64 PRNs. Detailed information on both sets can be found in <http://arxiv.org/abs/1011.2222>.

**Figure 1** Size of GH64 proteins in terms of the number of  $C\alpha$  atoms. PIDs are: 1mjc, 1gvp, 1ten, 1ris, 2acy, 1tlk, 1ayc, 1sha, 1CD8, 1d4t, 1e86, 2fgf, 1eif, 1pdo, 1h7i, 1amx, 1bj7, 1aep, 1gm6, 3rab, 1wba, 1rbp, 1eyl, 153L, 1fap, 1nsj, 1hro, 1jr8, 256b, 1ICE, 1arb, 1vlt, 1urn, 1amp, 1j8m, 1cjl, 1beb, 1OBP, 1b7f, 1hng, 1agd, 1aye, 1g4t, 1eov, 1bmt, 7tim, 1ce7, 1hwn, 2AAI, 1fbv, 1bf5, 1jly, 1dar, 1eun, 1rpx, 1bbp, 1bih, 1psd, 1b8a, 1ava, 1CVJ, 3eca, 3kbp, 1dio.

**Figure 2** Link count  $M$ , by protein size for GH64 PRNs.

### Search problem and search algorithm

We define a spin-glass like problem on a PRN and use the performance of a local search (a hill-climber in the fashion of the Metropolis algorithm with zero probability of assuming a higher temperature configuration) to assess the effect of changes in network topology, specifically average path length, on search performance. Starting at random points in a search space comprising  $\{0, 1, 2\}^N$  strings<sup>3</sup>, the problem is to find  $s$ , the unique globally optimal string defined by the DSSP output (Kabsch and Sander 1983) for a PRN reduced with the following rules: 0 represents H, I, and G, 1 represents E and B, and 2 represents others. The unique global optimum is reachable by maximizing the following fitness function which is derived from (Bryngelson and Wolynes, 1987):

$$\sum_{i=0}^N g(s_i, \mathbf{s}_i) + \sum_{i=0}^M f(e_i, s, \mathbf{s}).$$
 Define  $s_i$  as the current value of the  $i^{\text{th}}$  element in string  $s$ .  $g(s_i, \mathbf{s}_i) = 1$  if  $s_i = \mathbf{s}_i$  and 0 otherwise.

<sup>3</sup> Incidentally,  $3^N$  search spaces are common in discrete models of protein folding, e.g. 3 possible peptide bond torsion angles, and 3 possible bonds between hydrophobic (H) and polar (P) residues.

Define  $e_i$  as the  $i^{\text{th}}$  link in a PRN and  $e_i$  connects nodes  $j$  and  $k$ .  $f(e_i, s, \mathbf{s}) = 1$  if  $|s_j - s_k| = |\mathbf{s}_j - \mathbf{s}_k|$  and 0 otherwise. The  $g$  term ensures a unique global optimum<sup>4</sup> while the  $f$  term introduces frustration, i.e. the required ruggedness feature into the fitness landscape (Dill *et al* 1995, p.585).

The local search algorithm is a hill climber which at each time step, the value of a single randomly chosen element assumes a different value chosen randomly from  $\{0, 1, 2\}$ , and never moves down hill to less fit points. For each run, the hill climbing algorithm is iterated until  $\mathbf{s}$  is found, or the fitness function has been evaluated 1 million times. 20 independent runs are made per PRN. A total of 1280 (64 x 20) and 2640 (132 x 20) runs are made for GH64 and EVA132 respectively.

## Network Characteristics of PRNs

**Node degree** measures the number of contacts or direct neighbors a node has in a PRN. Gaci and Balev (2009) remarked on the homogeneity of node degree in their PRN called SSE-IN which only considers secondary structure elements. The mean node degree of their SSE-INS increased very slightly with protein size and fell within the range of 5 and 8. The absence of nodes with much higher degrees is attributed to the excluded volume effect which imposes a physical limit on the number of residues that can reside within a given radius around another amino acid. The mean node degree ( $K$ ) of the GH64 PRNs averages at 7.9696 with a standard deviation of 0.3126, and is independent of protein size (Figure 3).

**Figure 3** Node degree summary statistics for GH64 PRNs.

**Clustering** or transitivity reflects the cliquishness of nodes in a network: if node  $X$  connects to node  $Y$  and to node  $Z$ , how likely is it that nodes  $Y$  and  $Z$  are connected to each other? A convenient way to measure network clustering is by taking the average clustering of all nodes in a network to yield

the clustering coefficient as follows:  $C = \frac{1}{N} \sum_{i=1}^N \frac{2e_i}{k_i(k_i - 1)}$

where  $k_i$  is the degree of node  $i$ , and  $e_i$  is the number of links that exist amongst the  $k_i$  nodes (Watts and Strogatz 1998). Independent of protein size, the  $C$  values for GH64 PRNs ( $C_{\text{GH64}}$ ) are significantly higher than  $C_{\text{RANDOM}}$ , and closest to

<sup>4</sup> It also has a separable or a smoothing effect; without the  $f$  term, there is no interaction between variables.

$C_{\text{LATTICE4}}$  (Figure 4). Lattice $V$  is a linear lattice with  $V/2$  nearest neighbours to the left and to the right where possible.

**Figure 4**  $C_{\text{GH64}}$  values ( $\pm$  one standard deviation) compared with  $C_{\text{Lattice8}}$ ,  $C_{\text{Lattice4}}$  and the theoretical  $C$  values for regular ( $C_{\text{REGULAR}}$ ) and random ( $C_{\text{RANDOM}}$ ) networks of the same size (same number of nodes).  $C_{\text{RANDOM}} \sim K / N$ , and  $C_{\text{REGULAR}} = 3(K-2) / [4(K-1)]$ , where  $K$  is average degree and  $N$  is number of nodes (Watts 1999). We use  $K=8$  (see Figure3).

**Figure 5** Diameter, average ( $\pm$  one standard deviation) and median path length for GH64 PRNs.

**Figure 6** APLs of PRNs are much closer to APLs of random networks ( $\text{APL}_{\text{RANDOM}}$ ) than to APLs of regular networks ( $\text{APL}_{\text{REGULAR}}$ ).  $\text{APL}_{\text{RANDOM}} \sim \ln N / \ln K$ , and  $\text{APL}_{\text{REGULAR}} = N(N + K - 2) / [2K(N - 1)]$ , where  $K$  is average degree and  $N$  is number of nodes (Watts 1999). We use  $K=8$  (see Figure3).

The **average path length** (APL) of a network is the average length of a set of shortest paths between all node-pairs. The average path length for GH64 PRNs ( $\text{APL}_{\text{GH64}}$ ) increases logarithmically with increases in protein size (nodes) (Figure 5). When compared with average path lengths

of other canonical networks,  $APL_{GH64}$  is much shorter than the average path lengths of regular graphs ( $APL_{REGULAR}$ ) and approximate the average path lengths expected of random graphs ( $APL_{RANDOM}$ ) of the same size (Figure 6).  $APL_{GH64}$  is also much shorter than both  $APL_{LATTICE8}$  and  $APL_{LATTICE4}$  (Figure 6).

The **small-world property** is a combination of high clustering and short inter-nodal distances (average path length increases logarithmically with network size), two conditions that from the above exposition, GH64 PRNs satisfy.

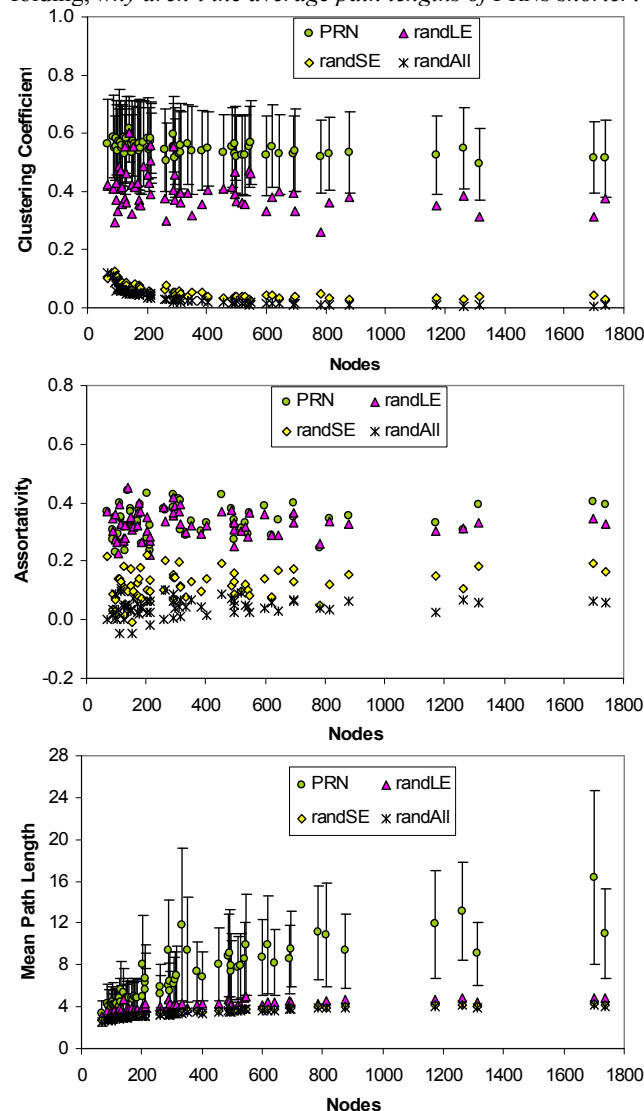

**Assortativity** refers to the extent that nodes associate or connect with their own kind. A common form of assortativity measured for PRNs is node degree. Positive degree-degree assortativity refers to the proclivity of nodes with small (large) degree to link with other nodes of small (large) degree. Using the method in (Newman 2002), Bagler and Sinha (2007) report degree-degree correlation coefficients up to 0.58, which is considered unusual for networks with biological origins. Nonetheless, the positive assortativity values could be correlated in a positive manner to protein folding speeds (Bagler and Sinha 2007). Similarly, we find positive degree-degree correlations in the GH64 PRNs independent of protein size. The assortativity values average at 0.3387 with a standard deviation of 0.0536, which is much higher than observed for randomized PRNs (randAll) (Figure 7). For randAll networks, PRNs are randomized in the usual manner by rewiring nodes while preserving node degrees and without introducing multiple links between nodes (Maslov and Sneppen 2002).

**Figure 7** The GH64 PRNs have positive degree assortativity, with values closest to those for Lattice4.

As with clustering (Figure 4), the assortativity values for GH64 PRNs are closest to Lattice4 (Figure 7). Bartoli *et al* (2007) commented that links encompassing a protein's backbone (which are short-ranged) is the main source of the relatively high levels of clustering in PRNs. We observed that short-range links (SE) are also responsible for much of the positive assortativity in PRNs. Figure 8 shows the effect of randomizing different sets of links in GH64 PRNs. Both clustering and assortativity levels show larger decreases when only the short-range links are randomized (randSE), compared with when only the long-range links are randomized (randLE). The APLs of PRNs are significantly reduced in both randSE and randLE networks. Hence it is possible, by randomizing only the long-range links, to rearrange the links of a PRN such that the APL is significantly reduced while preserving clustering and positive degree-degree assortativity coefficients at levels higher than would be in random graphs. Our question

is thus: if short inter-nodal distances are important for protein folding, *why aren't the average path lengths of PRNs shorter?*

**Figure 8** Effect of randomizing different sets of PRN links on Clustering Coefficient (top), Assortativity (middle), and Average Path Length (bottom). Error bars denote one standard deviation from the mean.

## Results and Discussion

Both accuracy and speed, i.e. finding the right structure consistently in biologically functional time, are important criteria in the protein folding problem. We measure accuracy of the local search in terms of *Success Rate (SR)*, which is the proportion of total runs (20) per PRN where the hill climber found the unique global optimum within 1 million evaluations. Speed of the local search is accessed by *avg\_evals*, which is the number of fitness function evaluations averaged over all runs with  $SR > 0.0$  per PRN. Configuration *A* is considered more favorable to protein folding than configuration *B* if the local search algorithm performs better, i.e. achieves a significantly higher SR and a significantly

lower avg\_evals, on *A* than on *B*. A *configuration* refers to a combination of network topology and fitness function. Search performance is affected by network size, larger networks are in general expected to be either more difficult to optimize and/or require more function evaluations. To remove this size effect, search performances between two configurations are compared on the set of common networks with SR > 0.0. The largest p-value of the Shapiro-Wilk test for SR and avg\_evals data is 0.03380715 and 1.072698e-07 respectively. This allows us to conclude, with at least 95% confidence, that both SR and avg\_evals data are not normally distributed, and to use the Wilcoxon method (paired) to test SR and avg\_evals data for significance. Following this procedure, the hypotheses in the following discussion are confirmed with at least 95% confidence.

## Experiment 1

The objective is to compare PRNs with lattices (“regular” graphs), i.e. how differences in their network topology affect search performance given the fitness function stated earlier. Lattice $V$  is a linear lattice with  $V/2$  nearest neighbours to the left and to the right where possible ( $V/2$  nodes at each of the two ends of the lattice chain will have fewer links than the rest of the nodes in the middle which will have  $V$  links each). The GH64 PRNs share several network characteristics with Lattice4 and Lattice8. For networks having the same number of nodes, PRNs have the same link density as Lattice8, and similar clustering and positive degree-degree assortativity levels as Lattice4 (Figures 9, 4 and 7 respectively).

**Figure 9** Link density by size for GH64 proteins on a log-log plot, compared with the same for Lattice4 and Lattice8. Link density is the fraction of actual links out of all possible links, i.e.  $2M / [N(N-1)]$ .

Using the fitness function defined earlier, the hill climber performed better when the network topology is PRN than when it is Lattice8 (Table 1). However, both are outperformed by Lattice4 (Table 1), which has a significantly longer APL (Figure 6). Lattice4 also produced twice as many networks with SR > 0.5, and seems more conducive to larger networks than either Lattice8 or PRN (Table 2). Hence, shorter inter-nodal distances do not guarantee better search performances. The shorter APLs of Lattice8 and of PRN are the result of more links (Figure 9), and the fitness function is such that additional links can increase frustration (more on this point in Experiment 4). Furthermore, the regular connectivity of a lattice network probably does not produce suitably functional surface structures like those of proteins (but see Table 7).

**Table 1** Result summary for Experiment 1

A	B	#	SR	avg_evals
Lattice8	<b>PRN</b>	49	A = B	A > B
<b>Lattice4</b>	Lattice8	53	A > B	A < B
<b>Lattice4</b>	PRN	56	A > B	A < B

# is the number of networks with SR > 0.0, common to both configurations *A* and *B*. Configurations with better overall search performances are **bolded**. These signs apply to all subsequent result tables. PRNs are from the GH64 dataset. Optimal strings for PRN and both Lattice4 and Lattice8 come from the DSSP output for proteins in the GH64 dataset (as explained earlier in the Method section).

## Experiment 2

The objective is to observe the effect of link randomization on search performance. By randomizing different sets of links in a PRN, it is possible to rearrange the links of a PRN such that the APL is significantly reduced (Figure 8). Further, by randomizing only the long-range links (randLE), it is also possible to significantly reduce APLs of PRNs and maintain clustering coefficients and positive degree-degree assortativity at levels higher than would be in random graphs (Figure 8).

**Table 3** Result Summary for Experiment 2

A	B	#	SR	avg_evals
randSE	randAll	64	A = B	A = B
PRN	<b>randLE</b>	55	A < B	A > B
PRN*	<b>randLE*</b>	115	A < B	A > B

PRNs are from the GH64 and where indicated by \*, the EVA132 dataset. randLE, randSE and randAll are as explained earlier, PRN networks produced by respectively randomizing only the Long-range links, only the Short-range links and all links. Optimal strings for all networks come from the DSSP output for GH64 proteins and where indicated by \*, the DSSP output for EVA132 proteins.

Compared to PRN, randomizing all links (randAll) and randomizing short-range links (randSE) increased SR to almost 100%, with a considerable decrease in avg\_evals (Table 2). There is no significant difference in terms of search performances between randSE and randAll (Table 3). But randAll and randSE networks lose much of the local organizational structure of PRN networks (Figure 8), and so probably do not produce suitably functional surface structures like those of proteins (see Table 7). *What is more interesting is that randomizing long-range links (randLE) significantly improved search performance over PRN (Table 3) for both GH64 and EVA132 datasets.* We revisit this point in Experiment 4, where an adjustment to the fitness function restores PRN to a favourable spot in the space of possible network configurations considered in this paper.

## Experiment 3

The objective is to compare the relative importance of short-range and long-range links to protein folding. There has been quite an evolution of thought in this area (Dill et al, 1995; Gö, 1983) and is by no means a settled issue. All three possible perspectives have been contemplated: (i) primacy of short-range interactions, (ii) primacy of long-range interactions, and (iii) non-dominance of either set of interactions.

**Table 2** Key summary statistics for results obtained in Experiments 1, 2 and 3

PRN s	Configuration	Median, Mean, Sd Success Rate (SR)	Proportion of networks with > 0.0 SR	Median avg_evals of networks with > 0.0 SR	Proportion of networks with > 0.5 SR	Median size of networks with > 0.5 SR
GH64	Lattice4	0.6000, 0.5727, 0.3142	62/64 = 0.9688	6158	35/64 = 0.5469	211
	Lattice8	0.2500, 0.3289, 0.3190	53/64 = 0.8281	7245	15/64 = 0.2344	185
	PRN	0.3250, 0.3383, 0.2569	56/64 = 0.8750	6264	14/64 = 0.2188	129
	randLE	0.3750, 0.4000, 0.2772	62/64 = 0.9688	5126	24/64 = 0.3750	134
	randSE	1.0000, 0.9977, 0.0139	64/64 = 1.0000	3609	64/64 = 1.0000	290
	randAll	1.0000, 0.9945, 0.0220	64/64 = 1.0000	3541	64/64 = 1.0000	290
	onlySE	0.0500, 0.1313, 0.2124	33/64 = 0.5156	4115	6/64 = 0.0938	134
	onlyLE	1.0000, 0.9070, 0.1466	64/64 = 1.0000	4262	62/64 = 0.9688	276
	delay07	0.3500, 0.3734, 0.2619	58/64 = 0.9063	5703	20/64 = 0.3125	146
	delay08	0.3500, 0.3703, 0.2735	57/64 = 0.8906	5926	18/64 = 0.2813	146
	delay09	0.3500, 0.3789, 0.2823	56/64 = 0.8750	5733	21/64 = 0.3281	153
	delay10	0.0500, 0.1273, 0.2074	33/64 = 0.5156	4115	6/64 = 0.0938	134
EVA132	PRN	0.2500, 0.3008, 0.2460	119/132 = 0.9015	9976	27/132 = 0.2045	145
	randLE	0.3500, 0.3553, 0.2508	120/132 = 0.9091	10580	33/132 = 0.2500	226

The first column gives the source of the PRN and optimal string *s*. Size of networks in the GH64 dataset has a median of 290 and is not normally distributed. The one-sample Kolmogorov-Smirnov two-sided test *p*-value = 2.220e-16. Size of networks in the EVA132 dataset has a median of 442 and is not normally distributed. The one-sample Kolmogorov-Smirnov two-sided test *p*-value is < 2.2e-16.

Compared with PRN, the use of only short-range links to guide the search (onlySE) reduced SR by 41% while using only long-range links (onlyLE) increased SR by 14% to almost 100% (Table 2). By examining both GH64 and EVA132 PRNs, we found that on average, only about 30% of all links in a PRN are long-range. The satisfaction of all links (constraints) in a PRN is necessary to achieve the globally maximal fitness value, and perfectly relaxed protein molecules as described by Gō (1983). Thus, the SR for onlyLE is quite remarkable and lends credence to the “primacy of long-range interactions” view (Dill *et al.*, 1995). In both GH64 and EVA132 PRNs, long-range interactions implicate on average about 60% of all nodes in a PRN. However, it has been proposed that only 30% of residues are crucial for folding (Dill 1999, p.1169).

Proteins exist in 3D physical space. The possibility of a long-range link may depend on some prior sequence of events to bring distant nodes on the polypeptide chain into close spatial proximity with each other. Hence, there is some dependency between links. But long-range links are not mere corollaries to short-range links. Gō (1983) argues that “...folding cannot be a simple unidirectional sequence of events going from smaller to larger structures; long-range interactions also play a determining role in secondary structures and there should be feedback of logic between the levels of organization”.

In our experiments, we observed that a slight delay in the use of long-range links to guide the hill climber significantly improved search performance (Table 4). In delayZ, the use of long-range links is delayed until the fraction of satisfied short-range constraints reaches Z/10. However, if long-range links are included only after all short-range links are satisfied, as in delay10, SR drops to levels similar to SR for onlySE (Table 2), i.e. it is as though long-range links are ignored in the search process completely. These results show that long-range links do help the satisfaction of short-range links in PRN (illustrating Go’s point), but the involvement of long-range

links in the search is more productive once some level of satisfaction (> 50%) in short-range links have occurred.

**Table 4** Result Summary for Experiment 3

A	B	#	SR	avg_evals
PRN	<b>delay07</b>	54	A < B	A > B
PRN	<b>delay08</b>	54	A < B	A > B
PRN	<b>delay09</b>	53	A < B	A = B

# is the number of networks with SR > 0.0, common to both configurations *A* and *B*. Configurations with better overall search performances are **bolded**. PRNs are from the GH64 dataset. delay07, delay08 and delay09 are, as explained in the text, PRN networks produced by delaying the consideration of long-range links when computing the fitness function until a proportion of short-range links are satisfied. Optimal strings for all networks come from the DSSP output for proteins in the GH64 dataset.

We collected the search points (strings) at the end of failed runs for one PRN (1wba) which failed fairly evenly under the different scenarios tested, and summarized their fitness values and Hamming distances from the global optimum. There is a negative correlation between fitness and distance. We find that runs which did not have enough opportunity to use long-range links to guide the search (onlySE, delay10) produced strings which are most distant and also least fit at the end (Figure 10). Even though the PRN strings are from failed runs, they are still more fit and closer to the global optimum than strings from delay10 or from onlySE.

## Experiment 4

The objective is to observe the effect of varying fitness contribution of links by link length on search performance, given the previous findings. To incorporate the outcome of experiment 3 into the optimization function, we added a weight factor into the *f* term for the experiments in this section

**Figure 10** Summarized fitness and hamming distance from global optimum (optimum) of strings produced by failed runs for 1wba PRN. Number of strings in PRN, delay07, delay08, delay09, delay10 and onlySE are 18, 16, 17, 18, 20 and 20 respectively.

as follows:  $\sum_{i=0}^N g(s_i, \mathbf{s}_i) + \sum_{i=0}^M f(e_i, s, \mathbf{s}, \omega)$ . There are three

options to  $\omega$ : (i) *eq* which assigns equal weight or fitness contribution to all links (this is the option used so far); (ii) *bh* which assigns more weight to links with shorter range; and (iii) *th* which assigns more weight to links with longer range. Let  $e_i$  link nodes  $j$  and  $k$ ,  $d = |j - k|$  and  $|s_j - s_k| = |\mathbf{s}_j - \mathbf{s}_k|$ . If  $\omega = eq$ ,  $f(e_i, s, \mathbf{s}, \omega) = 1$ . If  $\omega = bh$ ,  $f(e_i, s, \mathbf{s}, \omega) = 1/d$ . If  $\omega = th$ ,  $f(e_i, s, \mathbf{s}, \omega) = d$ . However,  $\omega = th$  produced 0.0 SR for GH64 PRNs, and therefore is clearly not a viable fitness function (This outcome is not contradictory to the onlyLE result in Experiment 3 because there, the fitness function assigns equal weights to all links). As such we restrict the following discussion to *bh* and *eq* options.

Compared with the *eq* option (Table 2), the *bh* option significantly improved search performance when PRN is used as the underlying network (Table 6). For both GH64 and EVA132, the number of networks with SR > 0.5 increased by at least 2.5 times (36/14 and 77/27), and there is also an increase of at least 55% in the median size of networks with SR > 0.5. Putting more weight on short-range than long-range links introduces a bias towards the satisfaction of short-range links and is akin to putting a delay on long-range links as we did in the delayZ runs where  $Z < 1.0$  (Experiment 3). However, with the *bh* option, both sets of interactions are present right from the start, so they have more interplay opportunities. And from the results just discussed, there appears to be a payoff to this. Also, PRN<sub>bh</sub> produced significantly better search performance than delay07<sub>eq</sub> (Table 5). Hence, the fitness function with the *bh* option appears to be more compatible to the suitability of PRNs to protein folding.

When  $\omega = bh$ , as in Experiment 1, search performance is still better when the underlying network topology is PRN than when it is Lattice8 (Table 5). However, unlike Experiment 2, search performance is no longer significantly better with randLE than with PRN. For both GH64 and EVA132, when  $\omega$

$= bh$ , there is no significant difference between PRN and randLE in terms of search performance (Table 5). Hence, the shorter APLs that randLE can produce (Figure 8) do not confer a search advantage. With this finding, we observe as in Experiment 1, that shorter APLs do not necessarily guarantee better search performance. However, in this case, no additional links are involved.

**Table 5** Result Summary for Experiment 4

A	B	#	SR	avg_evals
PRN <sub>bh</sub>	PRN	56	A > B	A < B
PRN* <sub>bh</sub>	PRN*	116	A > B	A < B
PRN <sub>bh</sub>	delay07	58	A > B	A < B
PRN <sub>bh</sub>	Lattice8 <sub>bh</sub>	56	A > B	A < B
randLE <sub>bh</sub>	Lattice8 <sub>bh</sub>	56	A > B	A < B
PRN <sub>bh</sub>	randLE <sub>bh</sub>	61	A = B	A = B
PRN* <sub>bh</sub>	randLE* <sub>bh</sub>	122	A = B	A = B

The ‘*bh*’ suffix is used to mark configurations which use the *bh* option; otherwise the default *eq* option is used. PRNs are from the GH64 and where indicated by \*, the EVA132 dataset. Optimal strings for all networks come from the DSSP output for GH64 proteins and where indicated by \*, the DSSP output for EVA132 proteins.

## Summary and Conclusion

In experiment 1, we observed that PRN is a more favourable network topology than Lattice8 for protein folding, but that shorter average path lengths (APLs) need not imply better search performance. In experiment 2, we reported that randomizing long-range links of protein residue networks (randLE) significantly improved search performance over (non-randomized) PRNs. In experiment 3, we found that long-range links play an important role to global optimization and that adding a delay to the involvement of long-range links in the search improved search performance. In experiment 4, we use a modified fitness function which assigns more fitness contribution to shorter links and found that indeed *PRN is a more favourable network topology than randLE for protein folding even though PRN has a significantly longer APL than randLE*.

Shorter APLs in PRNs imply more compactness in native state proteins. That PRNs do not have minimal or at least shorter APLs than they do agrees with the notion that native state proteins are not in the most compact conformation possible (Dill et al, 1995 p. 568).

With  $\omega = bh$  in Experiment 4, *PRNs appear to occupy a sweet spot between complete order and total randomness* PRNs outperformed Lattice8 in terms of search performance, and random graphs (e.g. randSE and randAll networks) are unlikely to produce viable protein structures (Vendruscolo et al 1999). What about randLE which produced a comparable search performance to PRN? randLE represent less plausible 3D structures than PRNs, but more plausible than randSE or randAll (Table 7).

Randomization of long-range links in PRNs (randLE) was performed while keeping node degree of PRNs invariant. Hence, our experiments also suggest that there can be explanations, other than the popular excluded volume argument, beneath the topological limits of PRNs. For

**Table 6** Key summary statistics for results obtained in Experiment 4

PRNs	Configuration	Median, Mean, Sd Success Rate (SR)	Proportion of networks with > 0.0 SR	Median avg_evals of networks with > 0.0 SR	Proportion of networks with > 0.5 SR	Median size of networks with > 0.5 SR
GH64	Lattice8_bh	0.5000, 0.5023, 0.3281	56/64 = 0.8750	4624	31/64 = 0.4844	203
	PRN_bh	0.5750, 0.5750, 0.3176	62/64 = 0.9688	4947	36/64 = 0.5625	208
	randLE_bh	0.5750, 0.5648, 0.3172	62/64 = 0.9688	5336	34/64 = 0.5313	208
	randSE_bh	1.0000, 0.8773, 0.2047	64/64 = 1.0000	3283	57/64 = 0.8906	213
	randAll_bh	1.0000, 0.8352, 0.2426	64/64 = 1.0000	3344	54/64 = 0.8438	212
EVA132	PRN*_bh	0.6000, 0.5614, 0.3176	124/132 = 0.9394	9219	77/132 = 0.5833	226
	randLE*_bh	0.6000, 0.5492, 0.3197	122/132 = 0.9242	9373	76/132 = 0.5758	274

The first column gives the source of the PRN and optimal string *s*. The ‘\*’ indicates the use of the EVA132 dataset. The ‘\_bh’ suffix indicates the use of the *bh* option in the fitness function.

**Table 7** FT-COMAR results for five random PRNs in GH64

PID	N	Lat8	PRN	randLE	randSE	randAll
153L	185	0	0	196	1501	1543
1arb	263	0	0	1319	2278	2221
1cjl	307	0	144	1132	2802	2870
1rpx	690	0	355	3208	6496	6589
1psd	808	0	651	4975	7559	7772

FT-COMAR (Vassura *et al.*, 2008) predicts a plausible 3D construction of a given contact map and threshold, and reports the Hamming distance between the given contact map and the contact map of the predicted structure. Hence, a larger value in this table implies that the given contact map is less plausible as a 3D structure. FT-COMAR works better for thresholds larger than the one we use, i.e. 7 Angstrom, and this affects the results for larger PRNs. Nonetheless, the results still favor PRN over randLE.

instance, both local (high clustering and positive assortativity) and global (short average path length) characteristics of PRN seem necessary to create favorable conditions for protein folding.

Finally, it could be worthwhile, to both protein folding studies and systems organization in general, to understand how the short-range and long-range links in proteins cooperate to create mutual satisfaction without either set necessarily dominating the process.

## Abstract

The nests of social insects are not only impressive because of their sheer complexity, but also because they are built from much smaller agents whose work is not centrally coordinated. A central question is therefore how this coordination can lead to such large scale structures. In this paper we present an individual based nest construction model from experimentally inspired rules. The coordination of the building process is achieved through three main ingredients: 1) stigmergy, which implies that the local configuration of the structure is the stimulus which determines how to continue, 2) body template, where the interaction between the ant's body and the growing structure determines the proportions of the emerging pattern, and 3) a construction "pheromone", a chemical compound capable of triggering building actions. Our simulations show that this simple set of coordination rules can reproduce the key features observed experimentally in the ant *Lasius niger*, notably the emergence of mushroom-like pillars and layered structures. A sensitivity analysis on the evaporation rate of the construction pheromone shows that a large range of architectures, from dynamic multilayered nests to compact sponge-like structures, can be produced with the same behavioural rules by simply modifying evaporation rate. We discuss the relevance of these results with respect to the variety of nest architectures found in social insects.

## Introduction
